PROCEEDINGS

OF THE

ROYAL SOCIETY OF MEDICINE

EDITED UNDER THE DIRECTION OF
THE EDITORIAL COMMITTEE

HONORARY EDITORS:
MAURICE DAVIDSON, M.D., and ERIC A. CROOK, M.Ch.
ASSISTANT EDITOR: J. M. BROWNE KUTSCHBACH, M.B., D.P.H.

VOLUME THE FORTIETH
SESSION 1946-47

NOVEMBER, 1946—DECEMBER, 1947

LONDON
LONGMANS, GREEN & CO., LTD., 6 & 7, CLIFFORD STREET, W.1.
1947

PROCEEDINGS
OF THE
ROYAL SOCIETY OF MEDICINE

Edited Under the Direction of the EDITORIAL COMMITTEE

Honorary Editors: MAURICE DAVIDSON, M.D., and ERIC A. CROOK, M.Ch.

Assistant Editor: J. M. BROWNE KUTSCHBACH, M.B., D.P.H.

VOLUME THE FORTIETH. *SESSION* 1946-47

OFFICERS:

President—Sir Maurice Cassidy, K.C.V.O., M.D.

Immediate Past-President—Sir Gordon Gordon-Taylor, K.B.E., M.S.

Vice-Presidents—(Being the Presidents or duly appointed Representatives of the Sections the names of which are given in brackets)—Stanley Rowbotham, M.D. (Anæsthetics); A. Dickson Wright, M.S. (Clinical); G. R. Cameron, F.R.C.P., F.R.S. (Comparative Medicine); M. Sydney Thomson, M.D. (Dermatology); L. R. Broster, O.B.E., M.Ch. (Endocrinology); H. J. Parish, M.D. (Epidemiology and State Medicine); H. P. Himsworth, M.D. (Experimental Medicine and Therapeutics); Sir Arthur MacNalty, K.C.B., M.D. (History of Medicine); Norman Patterson, F.R.C.S. (Laryngology); Maurice Davidson, M.D. (Medicine); Douglas McAlpine, M.D. (Neurology); James Wyatt, F.R.C.S. (Obstetrics and Gynæcology); H. Stobie, F.R.C.S., L.D.S.E. (Odontology); Harold Levy, F.R.C.S. (Ophthalmology); V. H. Ellis, F.R.C.S. (Orthopædics); H. V. Forster, M.C., M.B. (Otology); Denis Browne, F.R.C.S. (Pædiatrics); A. B. Rosher, (Pathology); Frank Cooksey, O.B.E., M.D. (Physical Medicine); A. Hedley Whyte, M.S. (Proctology); Aubrey Lewis, M.D. (Psychiatry); Hugh Davies, D.M. (Radiology); Sir James Walton, K.C.V.O., M.S. (Surgery); R. H. O. B. Robinson, F.R.C.S. (Urology).

Honorary Treasurers—J. B. Hunter, C.B.E., M.Ch.; C. E. Newman, M.D.

Honorary Librarians—E. K. Martin, M.S.; T. C. Hunt, D.M.

Honorary Secretaries—R. H. O. B. Robinson, F.R.C.S.; W. A. Pool, M.R.C.V.S.

Honorary Editors—Maurice Davidson, M.D.; Eric A. Crook, M.Ch.

Other Members of Council—Alice Bloomfield, F.R.C.S.; E. R. Boland, C.B.E., F.R.C.P.; L. R. Broster, O.B.E., M.Ch.; E. A. Cockayne, D.M.; V. Zachary Cope, M.S.; Macdonald Critchley, M.D.; E. R. Cullinan, M.D.; R. Davies-Colley, C.M.G., M.Ch.; Anthony Feiling, M.D.; Sir Archibald Gray, C.B.E., M.D.; Charles Harris, M.D.; H. L. Marriott, C.B.E., F.R.C.P.; Geoffrey Marshall, O.B.E., M.D.; M. Section of Anæsthetics

CONTENTS

December 6, 1946

	PAGE *Section*	*Volume*
DISCUSSION : SHOCK WITH SPECIAL REFERENCE TO ANÆSTHESIA	1–12	167–178
Professor H. N. Green	1	167
Dr. R. P. Harbord	6	172
Dr. R. J. Minnitt, Dr. Ronald Woolmer, Dr. Barnet Solomons	11	177
Dr. H. W. Loftus Dale, Dr. Stanley Rowbotham, Dr. R. P. Harbord, Professor H. N. Green	12	178

January 3, 1947

DISCUSSION : ANÆSTHESIA FOR ABDOMINO-PERINEAL OPERATIONS FOR CANCER OF THE RECTUM	13–20	263–270
Dr. Ronald Jarman	13	263
Dr. Frankis Evans	16	266
Mr. O. V. Lloyd-Davies	18	268
Dr. V. Eades Vessell, Dr. H. W. Loftus Dale, Dr. Victor Goldman	19	269
The President (Dr. Stanley Rowbotham), Dr. Frankis Evans	20	270

March 7, 1947

DISCUSSION ON LOCAL ANALGESIA	21–28	525–532
Dr. Norman R. James	21	525
Dr. Frederick Prescott	23	527
Mr. H. W. L. Molesworth	25	529
Dr. F. W. Roberts, Dr. S. G. Ransom, Mr. Harold Dodd	27	531
Dr. Stanley Rowbotham	28	532

April 11, 1947

DISCUSSION ON FURTHER EXPERIENCES WITH CURARE	29–38	593–602
Dr. Frederick Prescott (*in absentia*, read by Dr. R. H. Roberts)	29	593
Dr. Geoffrey Organe	32	596
Dr. Barnett Mallinson	34	598
Dr. A. C. Forrester, Dr. John Gillies	36	600
Dr. John Halton, Dr. L. O. Mountford, Dr. H. B. Wilson, Dr. Massey Dawkins, Dr. Cecil Gray	37	601
Dr. Barnett Mallinson	38	602

May 2, 1947

CONTROLLED RESPIRATION BY MEANS OF SPECIAL AUTOMATIC MACHINES AS USED IN SWEDEN AND DENMARK. [*Abstract*] E. Trier Moerch, M.B., B.S., M.D.Copenhagen	39	603
SKIN TEMPERATURE AS A CLINICAL AID DURING ANÆSTHESIA. [*Abridged*] J. Clutton-Brock, M.B., D.A.	43	607

Sudden Shifts of Body Fluids

PRESIDENT'S ADDRESS

By Professor G. R. Cameron, F.R.C.P., F.R.S.

Amongst the many unsolved problems of physiology and pathology is the fascinating one of re-distribution of body fluids when something goes wrong with the vessels and tissue spaces in which these fluids are normally contained. During the war period I had occasion to study this question from an unusual viewpoint, that of chemical warfare. I make no apology for the choice as a Presidential Address of what at first seems a highly specialized matter, for it will, I hope, become apparent that the focus of all such researches is one common to Medicine in its widest sense. Resolution of the problem will bring the answer to many difficulties, too often regarded as practical in contra-distinction to academic, an attitude I hold to be quite wrong.

When a highly irritant liquid such as lewisite or mustard gas is dropped on the skin in minute droplets, a blister forms in a few hours. The nature of this familiar disturbance is well known. It consists in the partial or complete separation of the avascular epidermis from the underlying vascular dermis by a fluid, at first free from cellular content but later fairly rich in white blood corpuscles. This fluid invariably contains other components of the blood, especially proteins and various salts. Sometimes the protein is in large amounts and may even approach a concentration of 6%, which means that the fluid is almost pure plasma from the circulating blood. The distribution of salts can be shown to obey the predictions which follow from a Gibbs-Donnan equilibrium and as such can be dismissed from this discussion without further comment. The epidermal covering or dome of the blister is so vitiated by the action of the causative agent and no doubt, too, by its separation from its nutritive bed, the dermis, that it invariably dies and later separates at the edges of attachment, thus presenting a problem to the surviving healthy structures around, a problem which is solved in the process we call regeneration. Two important features characterize the formation of such a blister, (1) the localized outpouring of blood plasma from the blood-vessels of the affected part, and (2) the detachment of the epidermis by this rush outwards of plasma. We know a good deal about the first mechanism, but very little about the second, although the important researches of Peters and his colleagues, and of Medawar, hold out promise of a solution in the discovery of proteolytic enzymes liberated after skin damage which may be responsible for loosening of the basement membrane which anchors the epidermis to the dermis.

Experimental pathology has long known that outpouring of a fluid follows injury by various means of blood-vessels, especially capillaries. There is an impressive

Sudden Shifts of Body Fluids

PRESIDENT'S ADDRESS

By Professor G. R. CAMERON, F.R.C.P., F.R.S.

AMONGST the many unsolved problems of physiology and pathology is the fascinating one of re-distribution of body fluids when something goes wrong with the vessels and tissue spaces in which these fluids are normally contained. During the war period I had occasion to study this question from an unusual viewpoint, that of chemical warfare. I make no apology for the choice as a Presidential Address of what at first seems a highly specialized matter, for it will, I hope, become apparent that the focus of all such researches is one common to Medicine in its widest sense. Resolution of the problem will bring the answer to many difficulties, too often regarded as practical in contra-distinction to academic, an attitude I hold to be quite wrong.

When a highly irritant liquid such as lewisite or mustard gas is dropped on the skin in minute droplets, a blister forms in a few hours. The nature of this familiar disturbance is well known. It consists in the partial or complete separation of the avascular epidermis from the underlying vascular dermis by a fluid, at first free from cellular content but later fairly rich in white blood corpuscles. This fluid invariably contains other components of the blood, especially proteins and various salts. Sometimes the protein is in large amounts and may even approach a concentration of 6%, which means that the fluid is almost pure plasma from the circulating blood. The distribution of salts can be shown to obey the predictions which follow from a Gibbs-Donnan equilibrium and as such can be dismissed from this discussion without further comment. The epidermal covering or dome of the blister is so vitiated by the action of the causative agent and no doubt, too, by its separation from its nutritive bed, the dermis, that it invariably dies and later separates at the edges of attachment, thus presenting a problem to the surviving healthy structures around, a problem which is solved in the process we call regeneration. Two important features characterize the formation of such a blister, (1) the localized outpouring of blood plasma from the blood-vessels of the affected part, and (2) the detachment of the epidermis by this rush outwards of plasma. We know a good deal about the first mechanism, but very little about the second, although the important researches of Peters and his colleagues, and of Medawar, hold out promise of a solution in the discovery of proteolytic enzymes liberated after skin damage which may be responsible for loosening of the basement membrane which anchors the epidermis to the dermis.

Experimental pathology has long known that outpouring of a fluid follows injury by various means of blood-vessels, especially capillaries. There is an impressive

may last several days, but as lewisite not uncommonly damages red corpuscles, leading to hæmolysis, and mustard gas has a direct injurious action on the bone-marrow, it would at first seem likely that the anæmia is a toxic one. I shall present evidence later on that other factors are also concerned.

If we turn to another chemical warfare agent, phosgene, this time an irritating gas which exerts its effects only after inhalation, we find that much the same sort of changes are induced in the tissues with which the phosgene comes into contact. There is a tremendous outpouring of fluid, rich in plasma proteins, into the voluminous air spaces of the lungs and this presents a serious problem to the organism in the form of pulmonary œdema. Only too frequently is it unsolved and acute mechanical anoxia develops with death from respiratory failure. Existing evidence shows that phosgene as such is not absorbed into the blood from the air spaces so that it does not contribute to the problem through its inherent chemical properties. Lewisite and mustard gas, on the other hand, as we were able to show, can be absorbed and lead to serious systemic complications. Accompanying the pulmonary œdema of phosgene inhalation is a series of changes in the blood pattern. One cannot fail to be impressed by the similarity of this pattern with that which develops after skin application of lewisite or mustard gas. Here again is a profound depletion of the circulating plasma without any noteworthy alteration of the total cell mass. In an animal with a large splenic reservoir, the goat for instance, there is often a temporary increase of the blood cell mass as might be predicted from the Barcroft theory of splenic function, and it has been shown, by American workers, that this phenomenon does not occur in the splenectomized subject. The plasma protein concentration also falls in amounts approximately balanced by the gain of protein in the lung œdema fluid as time goes on, whilst the behaviour of the hæmoglobin percentage, red cell count and hæmatocrit percentage likewise points to concentration of the blood. In other words, there is an exact parallel in the two types of conditions. In both much plasma leaves the vessels of the affected regions and there follows hæmoconcentration from loss of this blood plasma with its consequent disturbances of circulatory function, nitrogen metabolism and the rest. Other irritant gases, including inhaled lewisite and mustard vapour and certain of the smokes, give the same kind of pattern and it is obvious that we are dealing with a series of widely differing procedures which nevertheless have a common factor.

If we now turn to a completely different process, thermal burning, we meet with much the same set of disturbances once again. Thermal burns affecting an extensive skin area give a blood pattern which differs from that described with the gases only in the rapidity of its development. Here we see an extraordinary outpouring of fluid from the blood, almost a gush of fluid, in the first half-hour after burning. This fluid is the basis of the blistering and œdema of the burnt area. It is rich in protein and in fact may be pure plasma, as chemical analysis of the burn and blister fluid shows. Again we have the familiar sequence in the blood volume change, and there is also a sharp, though usually transient, rise in the non-protein nitrogen of the blood and often a mild or fairly severe anæmia. Surely we are face to face with the same kind of circulatory upset as in the previous examples.

Finally, there are some experiments which I believe have their value in our search for the meaning of these common phenomena. If large amounts of a hypertonic solution of glucose or saline be introduced into the subcutaneous tissues of a limb of a rabbit or goat, there follows quite rapidly a severe localized œdema due to much fluid leaving the circulation. Concentration of the circulating blood follows, as shown by the rising hæmoglobin percentage and red cell count and fall of the plasma volume, whilst the familiar non-protein nitrogen increase in the blood occurs at some stage or other and persists for a short time, and there is usually a secondary anæmia. In other words, the simple abstraction of fluid from the circulation gives us the line of simple experiments commencing with the observations of British workers in the early nineteenth century, and including the famous contributions of Augustus Waller, William Addison, Thomas Wharton Jones and Lister, culminating in the classical work of Cohnheim, Starling and Lewis; all such studies show how intense and rapid, yet ordered, is the local response of blood-vessels to injury. If further proof of the importance of this fluid loss is wanted we need only consider the systemic circulatory upset consequent upon a severe involvement of a richly vascular skin in injury. When a few milligrams of lewisite or mustard gas are allowed to soak into the surface tissues of an experimental animal there soon follows a series of changes in the circulating blood which are discussed below. It is not at all difficult to estimate with considerable accuracy the fluid portion of the whole blood by modern photometric methods, based on the principle long ago established by Whipple that minute amounts of dye when allowed to mix thoroughly with the blood give a measure of the fluid in which the dye is suspended, provided little of the dye escapes from that fluid. Certain high molecular dyes are known, such as trypan blue and its isomer T.1824, which form large colloidal complexes with the plasma proteins, especially the albumin fraction, and consequently leave the circulation rather slowly. The art of this method of calculating the blood volume lies in choosing a time after the dye has been injected into the vessels, short enough to exclude much loss of the dye, yet long enough to be sure that the dye has been uniformly distributed throughout the circulating blood and intimately mixed with its plasma. With certain precautions, the modern methods give uniform results and can be used for repeated estimations of the plasma volume over a short interval of time. After the skin application of these irritants there is found a regular decline in the plasma volume, sometimes to low levels, and this depression may last two or three days. The animal may die at this stage in a condition we called lewisite or mustard-gas "shock", a state in which the animal is cold and clammy, looks ill and is difficult to bleed because its veins are collapsed and its arterial blood-pressure is low. In not so severe cases, recovery follows in gradual fashion and in five to seven days there is great improvement in the clinical condition, whilst the plasma volume has once more returned to the normal level. Associated with these changes in the fluid portion of the blood are several other striking features. It can be shown that the hæmoglobin percentage, red cell count and packed cell volume (hæmatocrit percentage) rise during the period of plasma volume decline and at the height of the "shock" indicate a severe degree of concentration of the blood. Nevertheless, suitable calculations make it clear that there is really very little alteration in the total cell mass of the circulating blood. It thus appears that though the total blood volume has greatly decreased, this is wholly because of loss of its fluid portion. The same mass of red corpuscles is still in circulation but the blood is "thickened" through depletion of its watery phase. By careful weighings and chemical analyses of the tissues through which the lewisite or mustard gas has seeped, my colleague F. C. Courtice showed that most of this lost fluid could be accounted for as œdema fluid in the gas-contaminated regions.

Protein, too, leaves the circulation with the water. The total plasma proteins fall steadily for the first two to three days after lewisite application; at the same time a protein-containing fluid can be demonstrated in the region of lewisite action. A similar state of affairs arises after mustard-gas application. We are justified, therefore, in believing that because of some action of these irritants, large amounts of plasma are induced to leave the blood-vessels, especially the capillaries, and accumulate in the zone of influence of the irritants concerned.

During the period of "shock" with decreased plasma volume and plasma proteins, the blood urea level almost invariably rises but returns rapidly to normal when the blood volume recovers. This suggests a functional rather than a pathological disturbance of the kidney (Courtice). A mild degree of secondary anæmia is often found and many fields of biology. You will remember that Starling investigated the factors underlying absorption of fluids of varying tonicity from the body cavities and spaces and, in his own words, suggested that "there must be a balance between the hydrostatic pressure of the blood in the capillaries and the osmotic attraction of the blood for the surrounding fluids". When the capillary pressure increases there is increased transudation until equilibrium is established; with lessened capillary pressure there is predominant osmotic absorption of salt solution from the extravascular fluid until this becomes richer in proteins and the difference between its protein osmotic pressure and that of the intravascular plasma is equal to the diminished capillary pressure. The capillary wall thus acts as an inert filtration membrane, the motive force for fluid exchange being the hydrostatic pressure afforded by the blood-pressure and the osmotic pressure of the proteins in the plasma and tissue fluid. Starling was also aware that the tissues could exert a mechanical pressure, much less, it is true, than that exerted by the capillaries, and he actually measured this on many occasions. Such tissue pressure would oppose the force which presses fluid from the vessels. This balanced set of forces thus allows of the passage of water and crystalloids to and fro between the capillaries and the tissue spaces. Protein, however, requires another mechanism for absorption and this, Starling thought, resides in the lymphatics.

Fifty years of experimentation has done little to upset the Starling theory; indeed, more and more data have accumulated in support of what must be regarded as one of the great generalizations of physiology. The relative constancy of blood volume and tissue fluid volume has been established many times and technical improvements in measuring capillary pressure, osmotic pressure of plasma proteins, lymph flow and composition and tissue pressure have given results which are in remarkable agreement with the postulates of the theory. The capillary bed of the organism thus becomes a gigantic filtering surface, estimated by Krogh as being somewhat greater than 6,300 square metres in man, or as Landis so vividly puts it, equal to a minutely thin membrane three feet wide and four miles in length. Such a surface is ideal for rapid interchange of fluid. Over it drifts the blood at a pressure of 22 to 45 cm. water which tends to force plasma through the membrane. The fluid portion of the blood contains various protein fractions, for convenience labelled albumins and globulins, which exert an osmotic force of about 36 cm. water and this force attracts fluid through the filter bed into the main channel of flow. But the bed is of variable extent and its fluctuations lead to variation in filtering pressure and fluid flow. When the capillaries widen, as for example after warming, more fluid passes over the surface, the hydrostatic pressure increases, and filtration is enhanced. Hence more filtrate leaves the vessels for the tissues and œdema results. It must be emphasized that the filter has the important property of allowing only very small amounts of protein to pass through so that on one side it encloses water, crystalloids and very large molecules of protein, on the other side it is in contact with a salt solution containing very small amounts of protein. In this way there is maintained an additional motive force (the osmotic pressure) inherent in the large molecules within the capillaries. Despite this osmotic pressure being quite small in comparison with that of the crystalloids, it is an effective one, acting as it does almost unopposed, and being of a dimension not far removed from the hydrostatic pressure.

A little thought convinces one that the filter membrane plays a highly important part in equilibrium maintenance. At least 95% of the circulating protein is held back by the membrane in most parts of the body (Landis), though there are regions which permit a free passage of protein, notably in the liver and alimentary canal. Anything which makes the filter more leaky should, on the Starling theory, lead to great disturbance of fluid equilibrium for the proteins would pass to the tissue spaces and swing the balance of forces over to the side of attraction. In this way the counter-

complicated pattern of events we have recognized after the action of strong irritant liquids on the skin, thermal burning or inhalation of certain gases. It is not too much to suggest that many, if not all of the phenomena, follow upon the acute anhydræmia, no matter how it is induced. Further support for this view has been obtained through the careful experiments of my colleagues, F. C. Courtice and G. L. Foss, who have shown that much may be done to mitigate the serious features of gas anhydræmia by the intelligent use of plasma transfusion, whilst my assistants, J. D. Allen, R. F. G. Coles and J. P. Rutland and I have confirmed the beneficial action of plasma found by many other workers in the case of thermal burns. We also have obtained encouraging results in the treatment of the "shock" period of mustard-gas poisoning by using plasma. Of course, caution has to be exercised with this therapy for at certain stages of pulmonary œdema the administered fluid may leave the circulation for the lungs and add to the load of exudate already carried by the air spaces.

It would be wrong to leave this part of the story without referring to some of the compensatory mechanisms the anhydræmic organism calls into play when the crisis is precipitated. Perhaps the most important of these is the mobilization of fluid and protein from all available depots in the body, in an attempt to restore the depleted blood or rather plasma volume. The necessity for such emergency measures is of course shown by the grave results of continued anhydræmia, evidenced by the falling blood-pressure in the arteries and veins, the decline in body temperature—surely a manifestation of depressed metabolism—and the signs of functional upset in certain organs, especially the kidneys. That fluid is withdrawn from many sources is plainly shown by the dehydrated condition of many tissues, whilst the thirst the animal exhibits also suggests an urgent call for fluid from without. We have some reason to believe that fluid within the alimentary canal may also be drawn upon in this hour of need. Compensation for protein deficiency is indicated in the lag shown by the falling plasma protein curve which is a striking feature of all our examples, and indeed there may be postponement of the fall in protein concentration for a considerable period of time. This indicates that protein depots readily give up their labile reserves of protein (Whipple) and indeed they may be prepared to offer even more valuable gifts of protein from their resources.

In addition, there is evidence that some at least of the lost fluid and protein is returned to the circulation by way of the lymphatics which drain the sites involved in the fluid loss. We are familiar with the idea of increased lymph flow from burnt areas through the beautiful researches of Drinker and his associates. Courtice has employed similar methods in our own studies and has cannulated the lymphatics of limbs and even of the lungs in animals contaminated with poison gases. With truly remarkable skill he has followed the course of lymph flow for many hours after these injuries, and has given us convincing evidence that such flow is increased, both of water and protein. That such protein-rich lymph is added to the circulation is shown by the increase in thoracic duct flow at the period of greatest fluid loss from the blood-stream. Clearly, this form of compensation is of limited value and indeed may add to the troubles of the harassed organism by introducing some of the harmful chemical into the blood-stream.

Finally, the already well-known compensatory processes of vasoconstriction and blood shift affecting the vascular territories of the less "vital" tissues no doubt play an important part, but we have nothing to contribute to this field of research. I believe that much requires to be done in this domain for here we may find the secret of the case which ends in death.

How are we to put together the facts so briefly outlined in the above description? Exactly fifty years ago, the great physiologist, E. H. Starling, propounded his theory of fluid balance between the tissues and blood which has proved so illuminating in

many fields of biology. You will remember that Starling investigated the factors underlying absorption of fluids of varying tonicity from the body cavities and spaces and, in his own words, suggested that "there must be a balance between the hydrostatic pressure of the blood in the capillaries and the osmotic attraction of the blood for the surrounding fluids". When the capillary pressure increases there is increased transudation until equilibrium is established: with lessened capillary pressure there is predominant osmotic absorption of salt solution from the extravascular fluid until this becomes richer in proteins and the difference between its protein osmotic pressure and that of the intravascular plasma is equal to the diminished capillary pressure. The capillary wall thus acts as an inert filtration membrane, the motive force for fluid exchange being the hydrostatic pressure afforded by the blood-pressure and the osmotic pressure of the proteins in the plasma and tissue fluid. Starling was also aware that the tissues could exert a mechanical pressure, much less, it is true, than that exerted by the capillaries, and he actually measured this on many occasions. Such tissue pressure would oppose the force which presses fluid from the vessels. This balanced set of forces thus allows of the passage of water and crystalloids to and fro between the capillaries and the tissue spaces. Protein, however, requires another mechanism for absorption and this, Starling thought, resides in the lymphatics.

Fifty years of experimentation has done little to upset the Starling theory; indeed, more and more data have accumulated in support of what must be regarded as one of the great generalizations of physiology. Such a surface is ideal for rapid interchange of fluid. Over it drifts the blood at a pressure of 22 to 45 cm. water which tends to force plasma through the membrane. The fluid portion of the blood contains various protein fractions, for convenience labelled albumins and globulins, which exert an osmotic force of about 36 cm. water and this force attracts fluid through the filter bed into the main channel of flow. But the bed is of variable extent and its fluctuations lead to variation in filtering pressure and fluid flow. When the capillaries widen, as for example after warming, more fluid passes over the surface, the hydrostatic pressure increases, and filtration is enhanced. Hence more filtrate leaves the vessels for the tissues and œdema results. It must be emphasized that the filter has the important property of allowing only very small amounts of protein to pass through so that on one side it encloses water, crystalloids and very large molecules of protein, on the other side it is in contact with a salt solution containing very small amounts of protein. In this way there is maintained an additional motive force (the osmotic pressure) inherent in the large molecules within the capillaries. Despite this osmotic pressure being quite small in comparison with that of the crystalloids, it is an effective one, acting as it does almost unopposed, and being of a dimension not far removed from the hydrostatic pressure.

A little thought convinces one that the filter membrane plays a highly important part in equilibrium maintenance. At least 95% of the circulating protein is held back by the membrane in most parts of the body (Landis), though there are regions which permit a free passage of protein, notably in the liver and alimentary canal. Anything which makes the filter more leaky should, on the Starling theory, lead to great disturbance of fluid equilibrium for the proteins would pass to the tissue spaces and swing the balance of forces over to the side of attraction. In this way the counter-

complicated pattern of events we have recognized after the action of strong irritant liquids on the skin, thermal burning or inhalation of certain gases. It is not too much to suggest that many, if not all of the phenomena, follow upon the acute anhydræmia, no matter how it is induced. Further support for this view has been obtained through the careful experiments of my colleagues, F. C. Courtice and G. L. Foss, who have shown that much may be done to mitigate the serious features of gas anhydræmia by the intelligent use of plasma transfusion, whilst my assistants, J. D. Allen, R. F. G. Coles and J. P. Rutland and I have confirmed the beneficial action of plasma found by many other workers in the case of thermal burns. We also have obtained encouraging results in the treatment of the "shock" period of mustard-gas poisoning by using plasma. Of course, caution has to be exercised with this therapy for at certain stages of pulmonary œdema the administered fluid may leave the circulation for the lungs and add to the load of exudate already carried by the air spaces.

It would be wrong to leave this part of the story without referring to some of the compensatory mechanisms the anhydræmic organism calls into play when the crisis is precipitated. Perhaps the most important of these is the mobilization of fluid and protein from all available depots in the body, in an attempt to restore the depleted blood or rather plasma volume. The necessity for such emergency measures is of course shown by the grave results of continued anhydræmia, evidenced by the falling blood-pressure in the arteries and veins, the decline in body temperature—surely a manifestation of depressed metabolism—and the signs of functional upset in certain organs, especially the kidneys. That fluid is withdrawn from many sources is plainly shown by the dehydrated condition of many tissues, whilst the thirst the animal exhibits also suggests an urgent call for fluid from without. We have some reason to believe that fluid within the alimentary canal may also be drawn upon in this hour of need. Compensation for protein deficiency is indicated in the lag shown by the falling plasma protein curve which is a striking feature of all our examples, and indeed there may be postponement of the fall in protein concentration for a considerable period of time. This indicates that protein depots readily give up their labile reserves of protein (Whipple) and indeed they may be prepared to offer even more valuable gifts of protein from their resources.

In addition, there is evidence that some at least of the lost fluid and protein is returned to the circulation by way of the lymphatics which drain the sites involved in the fluid loss. We are familiar with the idea of increased lymph flow from burnt areas through the beautiful researches of Drinker and his associates. Courtice has employed similar methods in our own studies and has cannulated the lymphatics of limbs and even of the lungs in animals contaminated with poison gases. With truly remarkable skill he has followed the course of lymph flow for many hours after these injuries, and has given us convincing evidence that such flow is increased, both of water and protein. That such protein-rich lymph is added to the circulation is shown by the increase in thoracic duct flow at the period of greatest fluid loss from the blood-stream. Clearly, this form of compensation is of limited value and indeed may add to the troubles of the harassed organism by introducing some of the harmful chemical into the blood-stream.

Finally, the already well-known compensatory processes of vasoconstriction and blood shift affecting the vascular territories of the less "vital" tissues no doubt play an important part, but we have nothing to contribute to this field of research. I believe that much requires to be done in this domain for here we may find the secret of the case which ends in death.

How are we to put together the facts so briefly outlined in the above description? Exactly fifty years ago, the great physiologist, E. H. Starling, propounded his theory of fluid balance between the tissues and blood which has proved so illuminating in

Case for Diagnosis. ? Lichen Planus Hypertrophicus.—C. H. Whittle, M.D.

D. U., Corporal in the R.A.F., aged 24.

Four years' history of somewhat itchy nodules on front of shins, first appearing when he was in Rhodesia. These have been getting larger and more numerous. The largest lesions are oval about 2 in. long and 1½ in. in diameter, the long axis along the length of the shin : they are bluish-red warty nodes raised ¼ in. or more above the surface, with numerous keratin plugs in the follicles : there are smaller earlier outlying lesions. There is a similar bluish-red scaly plaque at the root of the penis ¾ in. in diameter.

Biopsy.—The sections show warty hyperplasia and hyperkeratosis of the epidermis and there is a fairly dense mixed cellular exudate in the corium, with some œdema. Stains for amyloid and for mucin show neither of these changes.

Wassermann reaction negative.

17.10.46: There are now some lichen planus papules on the wrists. He is shown because of the resistance to treatment of the warty lesions on the legs in such cases. Large doses of vitamin A are now being given, and results will be reported.

2.12.46: No change. C. H. W.

Hæmorrhagic Telangiectasia of Rendu-Osler-Weber, with No Family History.—C. H. Whittle, M.D.

D. L., an undergraduate, aged 23.

Seven years' history of persistent bluish-red macules on the backs of the hands; no symptoms. Also occasional nose-bleeds in same period.

The lesions are 1 mm. to 1 cm. in diameter and I think are made up of a network of fine blood-vessels. They are more noticeable in hot weather.

Family history.—His mother is a doctor; there is no traceable family history of a like condition. (*Note:* Pulmonary tuberculosis was diagnosed a year ago by mass radiography: symptomless, and no cough or sputum.)

Diagnosis.—This might be regarded as a case of vascular nævi, plus nose-bleeds, but I would prefer the diagnosis given. Another alternative is telangiectasia macularis eruptiva perstans, but the lesions are very few, limited to the hands, and unlike in this respect any of the other cases hitherto described (Weber, F. Parkes, Barber, H. W., Fox, Colcott *et al.*) There seem to be a few cases of true hæmorrhagic telangiectasia without any hereditary factor traceable, e.g. Whittle, C. H. (1945), *Brit. J. Derm.*, 57, 157.

Stock (1944, *Arch. Otolaryng.*, 40, 108-114), in a comprehensive review of the literature, concludes that "it is highly probable that in about 20% of the recorded cases the disease developed in the total absence of a family history of its occurrence. Whether the patients in these cases can transmit the disease to their progeny is not known".

Hæmorrhagic Telangiectasia of Rendu-Osler-Weber.—C. H. Whittle, M.D.

E. B., a married woman, aged 60.

Twenty years' history of bluish-red spots on tongue. Fifteen years' history of attacks of nose-bleeding. No hæmatemesis or melæna reported; no hæmaturia.

balance to hydrostatic pressure would be lessened and filtration would go on unrestricted until equilibrium was again asserted.

I believe that this is the basis of what was going on in the experiments I have described with irritants and burning. The rapid appearance in the tissues of a fluid rich in protein certainly suggests that the filter had let through these large molecules in a quite unusual fashion. My colleague, R. H. D. Short, was able to show that at a very early period after the application of lewisite or mustard gas to the skin, the capillaries became more permeable to a dye such as T.1824. Now this dye combines in some sort of way with the plasma albumin, as Ogston found out for us by means of ultra-centrifugation, so it is plain that capillary permeability had changed. Even after five minutes such an increase has been demonstrated by Short and by our colleagues, H. Cullumbine and H. N. Rydon, both in man and in animals. A similar disturbance can be shown to be at work in the lungs affected by irritant gases and smokes, though here we have to keep in mind an additional factor in the form of anoxia. These irritant gases frequently if not always induce early bronchial constriction which if continued leads on to anoxia. We owe to Landis and Drinker many reasons for believing that anoxia increases the permeability of capillaries; Landis, for instance, has shown that the minute vessels in the frog's mesentery may become three times as permeable in the presence of anoxæmia.

Whatever may be the factors concerned, the central point of our investigations is, I am firmly convinced, alteration of capillary permeability through the action of the gases, &c., on the tissues. We are faced with the greatest of all problems in pathology once more.

Cullumbine and Rydon demonstrated the production of Menkin's leukotaxin in tissues damaged by mustard gas, and this compound, together with the histamine-like substances of Lewis, is no doubt the intermediary in bringing about the capillary wall change which underlies increased permeability for plasma proteins. Once this view is accepted, most of the phenomena I have described follow in due course and the common story becomes an intelligible one.

But what of this fundamental permeability change which receives emphasis again and again in physiology and pathology? Is it a physical or chemical alteration in the surface membrane of the lining endothelial cells of the vessels, or can it be attributed to a loosening of the cement substance which binds together these cells, as was suggested originally by Sidney Ringer and again in recent years by Robert Chambers and his school? Are living processes concerned, bound up with the life of cells or must we look to the biophysicist for the answer?

The remarkable studies of Peters and Dixon on enzyme chemistry and chemical warfare agents have opened up a new way of approach to the permeability problem which may bring the solution, but are we to wait for the outbreak of fresh horrors of man's ingenuity to enable an organized and adequate attack on this most vital of problems?

BIBLIOGRAPHY

I have drawn freely on a series of reports prepared by colleagues and myself, working at the Chemical Defence Experimental Station, Porton, for the Ministry of Supply during the 1939-45 war years. Some of these reports are in process of publication. In addition, I have made use of the following papers :—

Otolaryng.*, 40, 108-114), in a comprehensive review of the literature, concludes that "it is highly probable that in about 20% of the recorded cases the disease developed in the total absence of a family history of its occurrence. Whether the patients in these cases can transmit the disease to their progeny is not known".

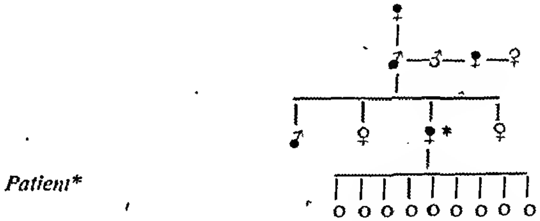
Hæmorrhagic Telangiectasia of Rendu-Osler-Weber.—C. H. WHITTLE, M.D.

E. B., a married woman, aged 60.

Twenty years' history of bluish-red spots on tongue. Fifteen years' history of attacks of nose-bleeding. No hæmatemesis or melæna reported; no hæmaturia.

Recently there arose a tendency for spots on tongue to bleed, and these led to her seeking advice. There were several telangiectatic spots on the sides and front of tongue, but I have electro-cauterized most of them. There are still spots on right thumb, left little finger and on the palate up to 6 mm. diameter, which tend to bleed into the skin.

Family history.—Paternal grandmother—"nosebleeds and spots"; father—was bleeder—died of hæmatemesis aged 46; father's sister—nose-bleeds; patient's brother—nose-bleeds and cerebral hæmorrhage. Patient's nine children so far unaffected, cf. Weber, F. Parkes (1939) *Brit. J. Derm.*, **51**, 468; (1938) *Brit. J. Derm.*, **50**, 94. Wigley, J. E. M., and Heggs, Gordon (1935) *Brit. J. Derm.*, **47**, 125.



FAMILY TREE. *Black indicates those affected.*

Darier's Disease and Generalized Pruritus.—LOUIS FORMAN, M.D.

H. B., aged 63, house painter. Has had many attacks of colic.

Fifteen years ago he had a perforated duodenal ulcer. Eight years ago, short attack of generalized pruritus.

He has noticed rough papules on the neck and groins for many years, and has complained of pruritus over the chest, axillæ and groins for two years.

On admission to hospital, there were excoriations over the trunk and horny papules on both sides of the neck, forearms, lower abdomen, hips, groins, and on skin near the anus. Some of the papules had been excoriated by scratching. A moist, raised plaque developed in the groin while he was in hospital.

Biopsy showed the characteristic changes of Darier's disease in a papule from the hip and in the plaque in the groin.

The treatment given was injections of testosterone, 20 mg. every other day for five weeks, with improvement of the pruritus.

Darier's disease is an inherited dysplasia of a nævoid character and as such may well be affected by endocrine changes. This may explain the development of the moist plaque during the administration of the testosterone.

Case for Diagnosis. ? Lichen Sclerosus.—H. J. WALLACE, M.D.

Mrs. A. T., aged 49. The eruption is said to have begun as a group of blisters eight years ago. Since then she has had other groups of blisters in different areas of the body from time to time, particularly the lower trunk and legs.

Past and family history.—Nothing relevant.

Aggregates of blisters have been observed to come and go over a period of months, often leaving scarring. A typical area consists of dome-shaped irritable papules, bluish-red in colour, varying in diameter from one to three millimetres and with a smooth surface. Many of these papules develop vesicles some of which become pustular. Mucous membranes not affected. No evidence of organic disease elsewhere. Complete blood-count normal. Blood Wassermann reaction negative. Biopsy shows hyperkeratosis; acanthosis with chronic inflammation of dermis; mild perivascular lymphocytic infiltration. She has received treatment with Fowler's solution, sulphapyridine, a course of bismuth injections, thyroid for long periods, liquor hydrarg. perchlor. by mouth for four months, all without effect.

A tentative diagnosis has been made of bullous lichen sclerosus.

Dr. L. Forman: This patient was under my care in 1939 and again in 1941. She developed blisters and superficial ulceration, which took two or three months to heal. Section of a group of thick roofed blisters on the abdomen showed thickening of the epidermis, intercellular œdema of the epidermis and the formation of blisters within the epidermis. Potassium iodide 5 grains (0·3 G.) t.d.s. was given for a week, and two new areas appeared on the right leg and ankle. They were circinate, erythematous patches with thick-roofed vesicles. 30% iodide ointment was applied to healed areas and small blisters appeared around the healed sites.

The diagnosis suggested was the erythema multiforme type of pemphigus.

Keratoderma Palmaris et Plantaris.—G. C. Wells, M.R.C.P. (for H. J. Wallace, M.D.).

H. L., aged 37, a labourer. This man has callosities of the palms and soles which first became painful about ten years ago. But he thinks that he has had "hard skin" on the hands and feet since childhood. He had to give up manual work six months ago because of the pain in the hands, but since then the lesions have remained unaltered.

There is nothing to suggest that he has had arsenic at any time.

Family history.—He tells us that of his four brothers and four sisters, one brother and one sister are affected. His mother and a sister of hers, and his maternal grandfather are also affected. One of his two daughters has a small lesion on one foot.

There was no consanguinity between his parents.

It is interesting to note that only the feet show the keratosis in all his affected relatives, whereas this patient has well-marked lesions of the hands as well.

There is a patchy symmetrical keratosis of the palms and soles, affecting mainly the pressure points, and there is some degree of pes cavus. Hyperidrosis is not a feature. There is not the diffuse involvement of surface that is seen in tylosis, nor are there the fine pitted lesions of punctate keratosis. While the general appearance suggests callosities, the persistence of the condition is against a simple mechanical origin.

The family history as far as it goes points to the trait being inherited as a regular Mendelian dominant. This is in keeping with previous observations on families showing keratoderma disseminatum palmaris et plantaris.

The President: I have seen one case, in a girl, but she was an unco-operative subject. At the time I tried to read up the literature, but it is very difficult to find any classification or grouping, and there seem to be very few cases published.

Lichen Nitidus.—J. R. Simpson, M.B. (for H. J. Wallace, M.D.).

Terence D., aged 9 years.

History.—The eruption was first noticed on the abdomen in March 1946. Since then there has been a steady spread to many other areas, with no evidence of resolution anywhere. There has been no itching. The mother gives no relevant past or family history. In particular there is no history of skin disease or of tuberculosis.

On examination.—The lesions are minute, wholly discrete papules, varying in size from 0·5 mm. to 2 mm. in diameter, but otherwise of uniform character. Their surfaces are glistening. Some are flat and some are dome-shaped, but all are easily palpable. There is no erythema or scaling and the colour is that of normal skin.

They are grouped together in colonies of varying size, distributed profusely on the trunk and limbs, and also on the penis, the forehead and right cheek. They are not related to the pilo-sebaceous follicles. The mucous membranes and the palms and soles are normal. Nothing abnormal was found on general examination.

Investigations.—X-ray of chest: No abnormality seen. Mantoux test: 1 : 10,000 negative; 1 : 1,000 negative. Biopsy from lesions on the right hypochondrium shows histological features characteristic of lichen nitidus.

Comment.—In view of the original conception that the ætiology of this condition was tuberculous he has been treated with calciferol, 100,000 i.u. daily. He has had

Recently there arose a tendency for spots on tongue to bleed, and these led to her seeking advice. There were several telangiectatic spots on the sides and front of tongue, but I have electro-cauterized most of them. There are still spots on right thumb, left little finger and on the palate up to 6 mm. diameter, which tend to bleed into the skin.

The President: I have seen one case, in a girl, but she was an unco-operative subject. At the time I tried to read up the literature, but it is very difficult to find any classification or grouping, and there seem to be very few cases published.

Lichen Nitidus.—J. R. SIMPSON, M.B. (for H. J. WALLACE, M.D.).

Terence D., aged 9 years.

History.—The eruption was first noticed on the abdomen in March 1946. Since then there has been a steady spread to many other areas, with no evidence of resolution anywhere. There has been no itching. The mother gives no relevant past or family history. In particular there is no history of skin disease or of tuberculosis.

On examination.—The lesions are minute, wholly discrete papules, varying in size from 0·5 mm. to 2 mm. in diameter, but otherwise of uniform character. Their surfaces are glistening. Some are flat and some are dome-shaped, but all are easily palpable. There is no erythema or scaling and the colour is that of normal skin.

They are grouped together in colonies of varying size, distributed profusely on the trunk and limbs, and also on the penis, the forehead and right cheek. They are not related to the pilo-sebaceous follicles. The mucous membranes and the palms and soles are normal. Nothing abnormal was found on general examination.

Investigations.—X-ray of chest: No abnormality seen. Mantoux test: 1 : 10,000 negative; 1 : 1,000 negative. Biopsy from lesions on the right hypochondrium shows histological features characteristic of lichen nitidus.

Comment.—In view of the original conception that the ætiology of this condition was tuberculous he has been treated with calciferol, 100,000 i.u. daily. He has had that for about a month. So far there has been no improvement, in fact fresh lesions have appeared since he has been having it.

Dr. F. F. Hellier: I am interested in what Dr. Simpson has said about the tuberculous ætiology. There is a good deal of evidence that the condition is closely related to lichen planus. In 1937 (Haynes, H., and Hellier, F. (1937) *Ann. Derm. Syph.*, Paris, 8, 192), I published a case in which there was typical lichen nitidus, very like the lesions in this child, and lichen planus. Histologically the lichen planus lesions were the usual ones, whilst the lichen nitidus papules showed the characteristic tuberculoid structure with giant cells. It would be an extraordinary coincidence if the two lesions were not related in some way. On the other hand, it is striking that each of the two lesions should keep its characteristic histology. Personally I feel that the two are closely related.

Dr. H. C. Semon: Other cases of the association have been recorded in the literature and I have recently seen a middle-aged woman with typical lichen nitidus lesions on the inner aspects of both thighs, pruritus vulvæ and labial œdema. It is more than likely that the lichen nitidus lesions were also present on the vulval mucous membrane as in fact they were on the buccal surface of the palate as a "granular stippling"—a characteristic feature of the eruption in this situation. It is significant in this connexion that lichen nitidus lesions are asymptomatic while those of lichen planus are decidedly the reverse.

Dr. P. J. Feeny: I have seen recently a case exactly like this, with, on the forearms, granuloma annulare. Until the biopsy is ready I am calling it lichen scrofulosorum.

Dr. F. Parkes Weber: This kind of lesion (lichen nitidus), does seem clinically to merge into lichen scrofulosorum. In some patients I think there is a little powderiness of the skin over the lesions. I imagine that the two conditions are in some way ætiologically allied.

Dr. J. R. Simpson: There was no evidence of tuberculosis in this case. I should like to say to Dr. Hellier that I do not subscribe to the tuberculosis theory of this condition, but I thought it might be of interest to use calciferol in this case to see whether it threw any further light upon it. With regard to the treatment with gold, Niles [1] has described a case which responded to treatment with gold sodium thiosulphate. Three injections were given and the case cleared up soon afterwards. Dr. Barber's cases [2] which responded were treated with tincture of iodine by mouth.

Effect of Calciferol on Lupus Vulgaris (Two Cases), Lupus Pernio and Boeck's Sarcoid.—I. R. MARRE, L.R.C.P., M.R.C.S.

Lupus Vulgaris (CASE I)

A. G., a man aged 67, was admitted to hospital on 6.5.46 for carcinoma of rectum, which proved inoperable.

He also had extensive lupus vulgaris of the lateral parts of his cheeks, zygomatic and temporal areas, involving both ears, the right one being bound down by scar tissue. The areas were curiously symmetrical and had been present for at least twenty years. The diagnosis was confirmed histologically.

He was given calciferol 50,000 units three times daily, and was kept on this dose until two weeks ago. There has been steady improvement and the lupus has been replaced by scar tissue with no evidence of activity. It is interesting that his advanced carcinoma and his marked anæmia did not interfere with the action of calciferol.

[Photographs were shown.]

Lupus Vulgaris (CASE II)

Henry E., aged 46, presented himself in July 1946, with extensive lupus vulgaris involving both cheeks and the adjacent parts of the neck.

The disease had been present for over thirty years, and he had had no treatment other than a twelve months' course of ultraviolet light, and various ointments.

He was given calciferol (50,000 units three times daily) at once, and has been on this dose ever since. He has shown marked improvement, large areas having healed.

Lupus Pernio

Mrs. J. S., aged 43, first attended hospital in September 1944, with a single blue *granulomatous* lesion, affecting the tip and about one-third of the area of her nose. She was treated by Kromayer lamp with "some benefit."

I first saw her in October 1945, when she thought the condition much the same.

The area was just as extensive, and diascopy showed apple-jelly nodules. She was given a short course of myocrisin, and did well, only to relapse shortly afterwards.

In January 1946 she was started on calciferol 50,000 units twice daily, and improvement was apparent, but slow. In April 1946 the dose was increased to 50,000 units three times daily, and the rate of improvement accelerated considerably, until in August 1946 the nose appeared normal. After three weeks' rest, however, the nose appeared much bluer, and treatment was recommenced in September 1946 again with marked improvement.

In October 1945 her chest X-ray was normal and her Mantoux (1 : 1,000) ++.

Boeck's Sarcoid

Mrs. M. A., aged 37. I first showed this woman to the Section in February 1944 (*Proc. R. Soc. Med.*, 37, 411), when the diagnosis of Boeck's sarcoid was agreed and confirmed histologically.

Before and since that time she has had every conceivable treatment with no good effect, and in fact she got steadily worse until May 1945. She still had her original lesions on the left big and second toes and the outer border of the left foot, a patch on the right third toe and outer border of the right foot, a large blue patch on the left cheek, and a swelling on the right side of the nose. This swelling increased enormously in size until in the early part of this year the lower part of the inner canthus on the right side was quite hidden.

On February 7, 1946, calciferol 100,000 units daily was started, and within a month there was a marked decrease in size of the nose.

In April 1946 the dose was increased to 150,000 units and she continued to improve very rapidly. She has continued on this dose with an occasional week's rest until two or three weeks ago, when the calciferol was stopped, and she is now very much better than she has been since 1943.

On the left foot the second toe is much smaller, and the swelling on the outer border has almost disappeared. On the right foot the little toe is smaller and the outer border seems normal. The nose has decreased considerably in size until it is almost normal and she finds herself able to go out without embarrassment.

Dr. J. E. M. Wigley: I should like to ask the exhibitor whether he has had any blood chemistry done in these cases to see whether there is any correlation between alterations in blood chemistry and clinical improvement or between alterations in blood chemistry and symptoms. In my department we have been working on about twenty cases recently, and it has been found that the serum calcium on the whole remains fairly constant, but the variations in the serum calcium do not seem to correspond in any way with the clinical improvement or lack of improvement.

The most important indication we have found has been in the chemistry not of the calcium, but of the allied substance—phosphorus. The fall in the serum alkaline phosphatase is likely to precede the rise in the serum calcium and also to be associated with the onset of symptoms. So far we have not found any serious signs in the way of calcium deposits: some cases have shown deposits, but on stopping the calciferol for a month or two they have disappeared.

The advisability of continuing the maximum dose, or of reducing the dose, or of stopping the calciferol altogether is bound up with the whole subject of the blood chemistry. Then the question arises whether calciferol acts locally or generally. This is a very difficult problem, and we are beginning to tackle it by applying the calciferol in an oily emulsion locally. It appears to be absorbed, and if we can produce the same results on the lesions with locally applied calciferol it will be a great advantage over the general use. We have also tried calciferol in cases where the histological findings were suggestive, rather than on what I may call the vague feeling that they were suitable. One case is of lupus miliaris facei, which has begun to respond to the local application of calciferol, after the general administration had failed. The histology of granuloma annulare is a little suggestive of tuberculosis, but in the one case in which we have tried calciferol, there has been no response to either local or general use of calciferol.

Dr. W. J. O'Donovan: Arising out of Dr. Wigley's remarks he will be interested to hear that I have under my care an elderly woman with severe lupus tumidus of her face of many years' standing and recent granuloma annulare on the back of her right hand. Under treatment with calciferol her lupus has disappeared. The granuloma annulare remains unaffected.

Dr. P. J. Feeny: If Dr. Wigley is able to show that calciferol applied locally will be of the same benefit as calciferol given internally, it will be a great advance in therapy, because serious toxic effects as distinct from symptoms of intolerance following administration internally have already been described in the literature. Apart from dermatological cases, a case of hypoparathyroidism has been published in which the dosage of calciferol used in dermatology caused arterial calcification (Eaton, J. C. (1946) *Biochem. J.*, 40, 52).

Dr. Prosser Thomas: I have tried calciferol locally in several cases of lupus vulgaris without appreciable response.

Sarcoidosis Treated with Calciferol.—BRIAN RUSSELL, M.D.

Mrs. E. B., aged 31.

History.—Two and a half years ago "cyst" on left cheek; was incised but recurred. One year ago similar swelling appeared on right cheek. Ten months ago swellings appeared in skin over both shoulders. Has suffered for many years from psoriasis.

Family history.—Father died of pulmonary tuberculosis twenty three years ago.

On examination (15.5.46).—In both cheeks are symmetrical subcutaneous, partly intradermal nodules of bluish colour with overlying telangiectatic erythema. Koilonychia. Psoriasis of elbows of long duration. Similar subcutaneous nodules about 1 cm. in diameter over upper deltoid region of both shoulders. No enlargement of lymphatic glands. Liver and spleen not palpable.

Investigations.—Biopsy from one of the arm lesions shows a granuloma of the dermis with a few giant cells and much round-cell infiltration but no caseation. Ziehl-Neelsen sections and Gram and modified Ziehl-Neelsen 5% sections show no organisms. Blood Wassermann and Kahn reactions negative. Graduated Mantoux test—weakly positive 1 : 1,000.

X-ray of hands—no abnormality detected, chest—marked hilar glandular enlargements.

Blood-count.—R.B.C. 5,730,000 per c.mm., Hb. 90%, C.I. 0·78%. W.B.C. 9,300 per c.mm. Differential: Polys. 84%, eosinos. and lymphos. 16%.

Sedimentation rates.—25.6.46: 25 mm. corrected; 24.7.46: 32 mm. corrected; 4.9.46: 24 mm. corrected.

Treatment.—The patient has received 50,000 units of calciferol twice a day since 9.6.46 and extra milk.

9.10.46: The lesions on the face are now softer and flatter. On the shoulders there remains only a discoloration. Involutionary changes therefore appear to be taking place in the cutaneous lesions but not in the glandular lesions, as two further X-ray films (7.8.46 and 2.10.46) reveal no alteration in the size of the hilar opacities. The erythrocyte sedimentation rate shows no improvement.

Case for Diagnosis. ? Reticulosis. ? Circumscribed Myxœdema.—BRIAN RUSSELL, M.D.

Mrs. L. V., aged 48.

History.—1943: Operation for adenomatous goitre. November 1944: pneumonia and ? pulmonary abscess, treated with sulphapyridine and penicillin. December 1945: noticed discoloration and thickening of the skin between brows and on cheeks and forearms. The condition is aggravated by hot tea or coffee, and by excitement and exertion. Catamenia have ceased. She has never been abroad but has had much exposure to sunlight in youth, having been a Land Girl on her father's farm 1914-18, a keen gardener and "outdoor person". She was very freckled in youth.

On examination (21.5.46).—Alert woman, of normal build. Waxy-looking, symmetrical, sharply marginated, infiltrated, intradermal red plaques of cartilaginous consistency between brows, over forehead in three finger-like processes, on malar regions and alæ nasi with associated telangiectasia. Eyebrows are thin. Tonsils are not enlarged. Has dentures. Scar of thyroid operation on neck. On sides of neck there is a patchy, reticular, brownish-red pigmentation with atrophic changes but without infiltration. On outer arms and extensor surface of forearms and proximal phalanges of fingers there is a confluent, papular, infiltrated, non-pruritic erythema, with numerous small, outlying, whitish nodules at shoulders. No areas of anæsthesia detected. No enlargement of lymphatic glands. Liver and spleen not palpable. Groups of firm, pinkish nodules just above both knees, and over inner calves.

Investigations.—Blood Wassermann and Kahn reactions negative. Graduated Mantoux test—weakly positive 1 : 10.000.

Blood-count.—Hb. 95%. W.B.C. 7,600 per c.mm. Differential: Polys. 57%, lymphos. 36%, monos. 5%, eosinos. 1%, basos. 1%.

Biopsy from infiltrated facial lesion shows thinned epidermis and very numerous, closely packed, pale endothelioid cells between the collagen bundles, involving almost the whole of the corium. Histology of arm lesions similar. No acid-fast bacilli in either.

X-ray of hands—no abnormality detected; chest—slightly increased hilar shadows, particularly right.

Treatment.—A dose of 400 r X-rays has been applied to the upper half of the lesion on the left forearm, but without effect other than slight increase in pigmentation.

Thyroid extract has been administered for the last two weeks before this meeting.

19.11.46: The patient complains of palpitations and throbbing in the throat since taking the thyroid tablets. This treatment has therefore been stopped. The dose was at first ½ grain twice a day but for the past two weeks has been 1 grain twice a day.

It is hoped that this case will be shown again at a future meeting, when Dr. Freudenthal will demonstrate some results of his histological investigations.

Dr. W. Freudenthal: May I suggest that this case belongs to the myxœdema group? In certain aspects, e.g. the aggregated dome-shaped papules, it has some clinical resemblance to P. B. Mumford and H. W. Barber's case of "myxœdema moniliforme" shown at the Royal Society of Medicine on 21.1.43 (*Proc. R. Soc. Med.*, 1943, 36, 286).

Miliary Lymphocytoma.—F. R. BETTLEY, M.R.C.P.

A. G., aged 48.

History.—At age 28 to 31, rash on backs of hands and forearms after exposure to sun and wind. In June, after exposure to the sun at the seaside, burning and weeping rash affecting the face. Similar attack in summer 1939, followed by itching spots which have appeared from time to time on the limbs and trunk ever since. The face still becomes red and sore after exposure to the sun. General health and family history, normal.

Present state.—On admission to hospital: Over the whole of the forehead, and to a less extent the zygomatic, malar and upper nasal regions the skin contains numerous closely set pinhead-sized semitranslucent grains. They are little raised above the surface of the surrounding skin. Over the trunk and limbs are scattered excoriations No enlargement detected of lymph glands, liver or spleen. General medical examination normal. X-ray of chest normal. W.R. negative. Blood urea normal, but Van Slyke renal function test 44% of normal.

Blood-count.—Hb. 93%. W.B.C. 5,800, neutros. 55%, lymphos. 40%, monos. 3%, eosinos. 1%.

Biopsy from forehead (Prof. R. W. Scarff): There is partial separation of the stratum corneum, but the epithelium is otherwise normal. In the middle of the dermis are circumscribed areas of lymphoid tissue. The smaller areas are made up of lymphocytes: the larger areas contain in addition lymphoblasts and large reticulo-endothelial cells, with well-marked follicular structure. In some of the sections there is a suggestion that some of these are related to sweat glands, but this relationship cannot be established in most instances.

Mercury-vapour lamp.—One-half and five-sixths of the normal first degree erythema dose was given to areas on the back of the thorax. After six hours both areas tested showed marked redness with œdema.

Dr. A. C. Roxburgh: I happen to have two patients—sisters—both of whom show this sort of condition. In both cases the lesions are on the temples and in one they are also on the left malar region. The lesions look like cysts but they are, I feel sure, the same as in this case.

Dr. Bettley: I believe that for the most part in the cases previously described this condition is stated to give rise to something larger in the way of tumours, up to the size of a pea, more grouped and localized and very often of a dark red colour. My recollection is that Epstein (S. Epstein, 1935, *Arch. Derm. Syph.*, 173, 181), who recorded, I think, four cases of this kind, mentioned one which has practically all the features of the case now shown—the light sensitivity, the itchy eruption over most of the body, and the quite small miliary lesions, rather suggesting, as Dr. Roxburgh says, cysts.

Dermatitis Bullosa Striata Pratensis.—H. GRUEBEL LEE, M.B., Ch.B. (introduced by Dr. I. MUENDE).

The patient, a woman aged 33, was first seen in the out-patients' department of Redhill County Hospital on October 7, 1946, complaining of irregularly shaped pigmented lesions on the forearms and legs, of five weeks' duration. The eruption strongly resembled that first described by Oppenheim in 1926 as Ottakring dermatitis, later as Bad und Wiesen dermatitis, and eventually as dermatitis bullosa striata pratensis; and the history confirmed this diagnosis.

The patient stated that the first signs of the affection were noticed shortly after weeding among parsnip beds at Hersham, near Walton-on-Thames. She spent four hours the first day and two the following morning, wearing a short-sleeved blouse, shorts and woollen stockings, but later removed the stockings on account of the heat. She was exposed to bright sunshine, and about forty-eight hours later she noticed wheals, with central tense bullæ, developing on the anterior surfaces of the legs and the anterior and inner aspects of the forearms. These were associated with severe irritation, which was relieved by pricking the blisters with a needle.

She had no further trouble, the affection resolving without any internal treatment or local application, and leaving brownish pigmentation. There is no previous history of dermatitis or of light sensitivity.

O'Donovan [1] reviewed two minor epidemics of dermatitis due to plant contact in the hot season, and pointed out that all the clinical characteristics of acuteness, the production of linear markings and blisters, and the artificial bizarre appearance of the eruption had developed in these cases as in previous records. The weed, *Agrimonia eupatoria*, was held as the cause of the epidemics, although O'Donovan was of the opinion that it is not the only cause of dermatitis bullosa striata pratensis in England. The late Dr. Robert Klaber [2] made a valuable contribution to the subject, and suggested that, in view of the fact that the eruption appeared to be due to light sensitivity following contact with certain plants, the title *phyto-photo-dermatitis* be employed in these cases.

I conducted patch tests on October 14 with leaf and stem of the same species of parsnip. The result, read after forty-eight hours, was positive with the leaf, and slightly more so in the case of the stem. I feel, however, that the test should have been followed by exposure of the part to the sun, or to the action of ultraviolet light; but unfortunately time did not permit.

2 KLABER, R. (1942) *Brit. J. Derm.*, 54, 193.

Dr. F. F. Hellier: In a group of cases of this condition on Salisbury Plain at the beginning of the war, it was at first thought that the men had been attacked by mustard gas, but a dermatologist diagnosed the true condition. I had a similar experience in Belgium where two girls had been handling parsnips, and it was thought that someone had put mustard gas on the parsnips. The true explanation was very simple. It was fine weather and the girls thought that it would be nice to peel the parsnips out of doors instead of indoors, with the result that they got a bullous dermatitis of the hands due to exposing the skin to sunlight after it had been sensitized by the juice of the parsnips.

Dr. C. H. Whittle: I recall two girls, whose occupation was canning parsnips, who showed a strikingly pellagrous type of eruption on the back of the hands. I saw these cases in the middle of the war and was unable to do anything about a follow-up or investigation, e.g. vitamin B estimation and therapy. The eruption followed exposure to the sun—it was in July—and came on while they were canning the parsnips. There have been reports in the literature of cases among canners who have shown the same type of eruption, e.g. Starck, Vera, 1944, *Acta. Dermat.-venereal.*, 25, 179 (quoted by Sulzberger, 1945 Year Book of Dermatology). In the 13 cases described the lesions followed exposure to the sun and involved the back of the hands, and forearms if exposed. 6 other women similarly exposed did not develop dermatitis. It is possible that the 13 reacting cases were deficient in vitamin B.

Section of Physical Medicine

President—FRANK COOKSEY, O.B.E., M.D.

[*November* 13, 1946]

Physiotherapy in an Accident Service

By Sir MAX PAGE, K.B.E., C.B., M.S.

THE importance of the application of physical methods in rehabilitation after injury is generally recognized, and calls for close collaboration between surgeon and physiotherapist.

The reaction of the surgeon to physiotherapy has varied widely through the ages. The classical writers recognized and sometimes described in detail the use of massage and exercises, but in general they directed the use of these procedures to the maintenance of health or the cure of disease rather than to rehabilitation after injury. It is, however, true that in the Hippocratic canon careful instructions are found on the use of massage and early movement after dislocation of the shoulder.

That great universalist, Galen, records his experiences when, early in his career, he was medical officer in charge of the gladiatorial school at Pergamum. I have not read his original account, but from abstracts it would appear that his main pride was in the fact that during his service he never lost the life of a wounded man; this he attributes to his method of wound dressing—which indeed was of a mildly antiseptic character. In his later writings on medical gymnastics his views are noticeably modern: he divided exercises into the passive type, including therein massage, and active exercises such as ball games and walking, and mixed, which he exemplified by horse riding.

His suggestive work was in some degree incorporated into the Arabian school of medicine but does not seem to have found any place in the practice of later European surgeons. It is indeed surprising how little reference to the restoration of function after injury is found in the writings of the latter. It remains a matter of opinion whether this was due to the greater toughness of frame and spirit of our forebears or whether to a more placid acceptance of disability after injury than is common nowadays. It should not be overlooked that the exploitation and advertisement of physiotherapeutic procedures by quacks led to a prejudice against their practice among the regular members of the profession. In any case the circumstances may and localized and very often of a dark red colour. My recollection is that Epstein (S. Epstein, 1935, *Arch. Derm. Syph.*, 173, 181), who recorded, I think, four cases of this kind, mentioned one which has practically all the features of the case now shown—the light sensitivity, the itchy eruption over most of the body, and the quite small-miliary lesions, rather suggesting, as Dr. Roxburgh says, cysts.

Dermatitis Bullosa Striata Pratensis.—H. GRUEBEL LEE, M.B., Ch.B. (introduced by Dr. I. MUENDE).

The patient, a woman aged 33, was first seen in the out-patients' department of Redhill County Hospital on October 7, 1946, complaining of irregularly shaped pigmented lesions on the forearms and legs, of five weeks' duration. The eruption strongly resembled that first described by Oppenheim in 1926 as Ottakring dermatitis, later as Bad und Wiesen dermatitis, and eventually as dermatitis bullosa striata pratensis; and the history confirmed this diagnosis.

The patient stated that the first signs of the affection were noticed shortly after weeding among parsnip beds at Hersham, near Walton-on-Thames. She spent four hours the first day and two the following morning, wearing a short-sleeved blouse, shorts and woollen stockings, but later removed the stockings on account of the heat. She was exposed to bright sunshine, and about forty-eight hours later she noticed wheals, with central tense bullæ, developing on the anterior surfaces of the legs and the anterior and inner aspects of the forearms. These were associated with severe irritation, which was relieved by pricking the blisters with a needle.

She had no further trouble, the affection resolving without any internal treatment or local application, and leaving brownish pigmentation. There is no previous history of dermatitis or of light sensitivity.

O'Donovan [1] reviewed two minor epidemics of dermatitis due to plant contact in the hot season, and pointed out that all the clinical characteristics of acuteness, the production of linear markings and blisters, and the artificial bizarre appearance of the eruption had developed in these cases as in previous records. The weed, *Agrimonia eupatoria*, was held as the cause of the epidemics, although O'Donovan was of the opinion that it is not the only cause of dermatitis bullosa striata pratensis in England. The late Dr. Robert Klaber [2] made a valuable contribution to the subject, and suggested that, in view of the fact that the eruption appeared to be due to light sensitivity following contact with certain plants, the title *phyto-photo-dermatitis* be employed in these cases.

I conducted patch tests on October 14 with leaf and stem of the same species of parsnip. The result, read after forty-eight hours, was positive with the leaf, and slightly more so in the case of the stem. I feel, however, that the test should have been followed by exposure of the part to the sun, or to the action of ultraviolet light; but unfortunately time did not permit.

2 KLABER, R. (1942) *Brit. J. Derm.*, 54, 193.

Dr. F. F. Hellier: In a group of cases of this condition on Salisbury Plain at the beginning of the war, it was at first thought that the men had been attacked by mustard gas, but a dermatologist diagnosed the true condition. I had a similar experience in Belgium where two girls had been handling parsnips, and it was thought that someone had put mustard gas on the parsnips. The true explanation was very simple. It was fine weather and the girls thought that it would be nice to peel the parsnips out of doors instead of indoors, with the result that they got a bullous dermatitis of the hands due to exposing the skin to sunlight after it had been sensitized by the juice of the parsnips.

Dr. C. H. Whittle: I recall two girls, whose occupation was canning parsnips, who showed a strikingly pellagrous type of eruption on the back of the hands. I saw these cases in the middle of the war and was unable to do anything about a follow-up or investigation, e.g. vitamin B estimation and therapy. The eruption followed exposure to the sun—it was in July—and came on while they were canning the parsnips. There have been reports in the literature of cases among canners who have shown the same type of eruption, e.g. Starck, Vera, 1944, *Acta. Dermat.-venereal.*, 25, 179 (quoted by Sulzberger, 1945 Year Book of Dermatology). In the 13 cases described the lesions followed exposure to the sun and involved the back of the hands, and forearms if exposed. 6 other women similarly exposed did not develop dermatitis. It is possible that the 13 reacting cases were deficient in vitamin B.

in the special fracture and accident clinics now common, the average standard of results shows a considerable advance on those of twenty years ago. The part played by surgeon and physiotherapist in these organizations is by no means rigidly fixed and is subject to considerable variation, but I will put forward a scheme which I think can be a successful one, fully admitting that wide diversity in method is necessary in order to suit different types of hospital and the varying personalities involved.

We have observed that in the past both the physiotherapist as well as the surgeon can be successful organizers of fracture departments. Not unnaturally I favour control by a surgeon and the organization I roughly sketch is founded mainly on experience in a large teaching hospital. The working medical personnel of the team should consist of a surgical director and one or two senior assistants together with corresponding house officers, two plaster Sisters and two or three certificated physiotherapists. The numbers in each category will clearly depend on the size of the clinic. The physiotherapists should take their instructions direct from the surgeon in charge; they should be handpicked for the job. From their training a reasonable knowledge of the standard methods of treatment may be assumed. but it is of great importance that they should possess firm personalities and have the ability to inspire their patients to work—in the sense of carrying out active movement. These ladies should be closely incorporated in the team, attending both ward rounds and outpatient clinics. The medical officer in charge of the department of physical medicine will only come into the picture as a consultant, the manner of which I will refer to later.

Physiotherapy departments tend to become overloaded with a mass of human material. Unless regular and rigorous checks are imposed a certain number of patients continue under treatment for months with little benefit to themselves and to the prejudice of the more deserving. It is in the main department, so often the dumping ground filled by various overworked clinicians, that this state of affairs is most in evidence: but similar crowding may affect the accident service if certain precautions are not taken. Overloading can be avoided or reduced if the needs of each individual case for physiotherapy are carefully estimated. First, most children, the subject of fracture, require little or no physiotherapeutic help in order to make a complete and speedy recovery. Adults should be classified into four groups in accordance with which the time they spend with the therapist may be determined. My idea of these groups is as follows:

(1) The enterprising—possessed of a love of personal independence and an attitude of self-help.
(2) The average co-operator.
(3) The poor-spirited and self-centred type.
(4) The non-co-operator derived from group 3 or such reasons as interest in compensation or a love of sympathy.

The physiotherapist in handling group 1 has only to make clear to the patient what freedom is permissible and demonstrate the appropriate exercises.

Group 2 will require more help and supervision and sometimes a certain amount of auxiliary treatment of the nature of massage or faradism.

It is those in the remaining two groups that strain our patience and judgment to the utmost. They should be brought before the medical officer i/c of Physical Medicine at a weekly consultation. At this consultation his opinion as to suitable treatment for difficult cases or those hanging fire is obtained and the psychological

remind us that a good recovery after injury is effected often enough without the intervention of any specialized treatment.

Even in the eighteenth century among surgical writers it is only John Hunter who approaches the problems of injury scientifically. His study of the physiology of muscular action and its application to the treatment of stiff joints remains a landmark. Surgeons as a whole, however, in the treatment of fractures continued to concentrate on methods of fixation: movement was left to return as it might after firm union was present. Adherents of the Ling school of gymnastics, established in 1816, and of the Zander system of mechanotherapy (1864) certainly used their special procedures in some cases of disability after injury, but these methods were not incorporated into the normal practice of current surgery.

It was undoubtedly Lucas-Championnière who first attacked the ruling faith in the value of rigid and prolonged fixation for all fractures, and I think his work in this respect deserves fuller recognition than it has so far received. One may recall that he was a general surgeon practising in Paris and one who had early in his career provoked the enmity of some of his colleagues on account of his prompt and ardent support of Lister. He published "Le Mouvement est la Vie" in 1880 and in 1886 first announced his method of treating fractures by mobilization and massage. It is evident that his suggestions met with a chilly reception for in his later book entitled "Le Mobilisation et le Massage dans le Traitement de Fractures" he says "Le public est peu preparé à accepter ce traitement revolutionnaire. Le monde médical n'y est pas beaucoup plus preparé que le public." He approached the problem with caution and selective judgment. At first he applied the method only to fractures of the lower end of the radius and of the fibula; subsequently to the upper extremity of the humerus. He recognized its limitations in the management of the major fractures of the long bones of the lower limb and he was always an advocate of the operative suture of the broken patella or olecranon. He laid great importance on massage of the limb soon after injury and instructed his students and assistants in a simple technique, being somewhat critical of the existing school of massage.

I think one of the reasons for the poor support given to Lucas-Championnière was the counterattraction exercised by the methods of open fixation of fractures which were introduced about the same time by Lane and Lambotte. This new technique undoubtedly made a strong appeal to the enterprising young surgeon—a nice piece of carpentry and a good-looking radiograph seemed to terminate his responsibility. In this country it was not till 1912 that a successful out-patient clinic based on Lucas-Championnière's teaching was organized by Dr. J. B. Mennell at St. Thomas's Hospital.

In the first great war the demand for systematic rehabilitation after injury was met by the organizations inspired by Sir Robert Jones and his school. The application of most of the conceivable forms of physical energy were then or later tried out. By a gradual process of trial and failure those found useful have been incorporated into the body of physiotherapeutic practice to-day.

In this period a break in the traditional methods of fracture management should be remembered, viz. that of Bohler of Vienna. In his clinic he obtained good results and shortened the average period of disability by postural treatment coupled with systematic active exercise; all forms of physiotherapy being dispensed with. I think his teaching has exerted a considerable influence on the practice of fracture clinics in this country.

With this wealth of experience behind us we may ask what position in this relationship we have arrived at to-day. There is, I think, general agreement that.

in the special fracture and accident clinics now common, the average standard of results shows a considerable advance on those of twenty years ago. The part played by surgeon and physiotherapist in these organizations is by no means rigidly fixed and is subject to considerable variation, but I will put forward a scheme which I think can be a successful one, fully admitting that wide diversity in method is necessary in order to suit different types of hospital and the varying personalities involved.

We have observed that in the past both the physiotherapist as well as the surgeon can be successful organizers of fracture departments. Not unnaturally I favour control by a surgeon and the organization I roughly sketch is founded mainly on experience in a large teaching hospital. The working medical personnel of the team should consist of a surgical director and one or two senior assistants together with corresponding house officers, two plaster Sisters and two or three certificated physiotherapists. The numbers in each category will clearly depend on the size of the clinic. The physiotherapists should take their instructions direct from the surgeon in charge; they should be handpicked for the job. From their training a reasonable knowledge of the standard methods of treatment may be assumed but it is of great importance that they should possess firm personalities and have the ability to inspire their patients to work—in the sense of carrying out active movement. These ladies should be closely incorporated in the team, attending both ward rounds and outpatient clinics. The medical officer in charge of the department of physical medicine will only come into the picture as a consultant, the manner of which I will refer to later.

Physiotherapy departments tend to become overloaded with a mass of human material. Unless regular and rigorous checks are imposed a certain number of patients continue under treatment for months with little benefit to themselves and to the prejudice of the more deserving. It is in the main department, so often the dumping ground filled by various overworked clinicians, that this state of affairs is most in evidence: but similar crowding may affect the accident service if certain precautions are not taken. Overloading can be avoided or reduced if the needs of each individual case for physiotherapy are carefully estimated. First, most children, the subject of fracture, require little or no physiotherapeutic help in order to make a complete and speedy recovery. Adults should be classified into four groups in accordance with which the time they spend with the therapist may be determined. My idea of these groups is as follows:

(1) The enterprising—possessed of a love of personal independence and an attitude of self-help.
(2) The average co-operator.
(3) The poor-spirited and self-centred type.
(4) The non-co-operator derived from group 3 or such reasons as interest in compensation or a love of sympathy.

The physiotherapist in handling group 1 has only to make clear to the patient what freedom is permissible and demonstrate the appropriate exercises.

Group 2 will require more help and supervision and sometimes a certain amount of auxiliary treatment of the nature of massage or faradism.

It is those in the remaining two groups that strain our patience and judgment to the utmost. They should be brought before the medical officer i/c of Physical Medicine at a weekly consultation. At this consultation his opinion as to suitable treatment for difficult cases or those hanging fire is obtained and the psychological

remind us that a good recovery after injury is effected often enough without the intervention of any specialized treatment.

Even in the eighteenth century among surgical writers it is only John Hunter who approaches the problems of injury scientifically. His study of the physiology of muscular action and its application to the treatment of stiff joints remains a landmark. Surgeons as a whole, however, in the treatment of fractures continued to concentrate on methods of fixation: movement was left to return as it might after firm union was present. Adherents of the Ling school of gymnastics, established in 1816, and of the Zander system of mechanotherapy (1864) certainly used their special procedures in some cases of disability after injury, but these methods were not incorporated into the normal practice of current surgery.

It was undoubtedly Lucas-Championnière who first attacked the ruling faith in the value of rigid and prolonged fixation for all fractures, and I think his work in this respect deserves fuller recognition than it has so far received. One may recall that he was a general surgeon practising in Paris and one who had early in his career provoked the enmity of some of his colleagues on account of his prompt and ardent support of Lister. He published "Le Mouvement est la Vie" in 1880 and in 1886 first announced his method of treating fractures by mobilization and massage. It is evident that his suggestions met with a chilly reception for in his later book entitled "Le Mobilisation et le Massage dans le Traitement de Fractures" he says "Le public est peu preparé à accepter ce traitement revolutionnaire. Le monde médical n'y est pas beaucoup plus preparé que le public." He approached the problem with caution and selective judgment. At first he applied the method only to fractures of the lower end of the radius and of the fibula; subsequently to the upper extremity of the humerus. He recognized its limitations in the management of the major fractures of the long bones of the lower limb and he was always an advocate of the operative suture of the broken patella or olecranon. He laid great importance on massage of the limb soon after injury and instructed his students and assistants in a simple technique, being somewhat critical of the existing school of massage.

I think one of the reasons for the poor support given to Lucas-Championnière was the counterattraction exercised by the methods of open fixation of fractures which were introduced about the same time by Lane and Lambotte. This new technique undoubtedly made a strong appeal to the enterprising young surgeon—a nice piece of carpentry and a good-looking radiograph seemed to terminate his responsibility. In this country it was not till 1912 that a successful out-patient clinic based on Lucas-Championnière's teaching was organized by Dr. J. B. Mennell at St. Thomas's Hospital.

In the first great war the demand for systematic rehabilitation after injury was met by the organizations inspired by Sir Robert Jones and his school. The application of most of the conceivable forms of physical energy were then or later tried out. By a gradual process of trial and failure those found useful have been incorporated into the body of physiotherapeutic practice to-day.

In this period a break in the traditional methods of fracture management should be remembered, viz. that of Bohler of Vienna. In his clinic he obtained good results and shortened the average period of disability by postural treatment coupled with systematic active exercise; all forms of physiotherapy being dispensed with. I think his teaching has exerted a considerable influence on the practice of fracture clinics in this country.

With this wealth of experience behind us we may ask what position in this relationship we have arrived at to-day. There is, I think, general agreement that.

in the special fracture and accident clinics now common, the average standard of results shows a considerable advance on those of twenty years ago. The part played by surgeon and physiotherapist in these organizations is by no means rigidly fixed and is subject to considerable variation, but I will put forward a scheme which I think can be a successful one, fully admitting that wide diversity in method is necessary in order to suit different types of hospital and the varying personalities involved.

Group 2 will require more help and supervision and sometimes a certain amount of auxiliary treatment of the nature of massage or faradism.

It is those in the remaining two groups that strain our patience and judgment to the utmost. They should be brought before the medical officer i/c of Physical Medicine at a weekly consultation. At this consultation his opinion as to suitable treatment for difficult cases or those hanging fire is obtained and the psychological

outlook of the individual is discussed. It may also be that he is specially interested in some of the snags of an accident service, such as suspected ruptures of the supraspinatus tendon, the condition known as frozen shoulder, or even low back pain.

The ideas I have roughed out apply to what appear to be straighforward cases and I will not confuse the issue by discussing the management of nerve injuries or other complications.

A word on Rehabilitation Centres. During the war these have fully proved their value in the management of bulk casualties. I am not sure of the degree to which they can be usefully employed in normal civil life. I think that in a well-established accident clinic most cases of injury can be seen through to full recovery by the team primarily responsible for their treatment. "Passing the buck", however, is always popular and sometimes it benefits the patient. Certainly the final tuning up after major injuries is best conducted in fair-sized classes, but God forfend the time when everyone who sustains a fracture thinks he cannot return to work till he has passed through a rehabilitation centre.

Dr. John H. Crosland: I would like to outline a few methods as to how we, as physical medicine specialists, can assist the orthopædic surgeon to attain the common aim of the fullest possible restoration of function to the patient.

A large number of orthopædic patients are perfectly healthy individuals leading a normal active life until they are knocked down by a bus, or sustain some similar damage. Many of these may be kept in bed for months and, during this time, unless they are helped, they more or less rapidly deteriorate both physically and mentally. It is obvious that such deterioration will also retard recovery of the actually traumatized part. In order to prevent this, the patient should be visited daily by a competent physiotherapist, and every part of his body except that immobilized by the surgeon, or that which when moved will interfere with such immobilization, should be given a full range of active movement. Breathing exercises and active contractions of abdominal and back muscles are all very important and can be given very adequately in the prone position.

Perhaps the cases requiring the most constant and patient treatment of this type are those condemned for a year or more to a plaster bed. Yet all that work is well rewarded when it is time for the patient to get up and it is seen how quickly he walks normally and how relatively good his general muscle tone can be.

I will pass rapidly over such small but important points as leaving a window over the knee-joint in a full-length leg plaster so that the patella can be passively moved twice daily; or, as advocated by some, of leaving another window in such a plaster over the quadriceps so that faradic stimulation may be given, or of leaving adequate room in a plaster so that full toe movements can be given, and come to one of the biggest bugbears. I refer to the stiff knee-joint following prolonged extension of a fractured shaft of femur in a Thomas's splint.

Generally speaking, the earlier a joint can be moved, the less likely is it to become stiff and so I propose to outline a method used to move knee-joints adopted by the orthopædic surgeon at Ashbridge E.M.S. Hospital. The idea is that the leg below the knee shall rest on the hinged extension portion of the Thomas's splint, and skin traction be applied in the normal way with the cord bearing the weight passing over a pulley at the end of the bed. The splint itself must be wide enough for the patient's foot and the hinged portion to pass inside it; it is fixed in abduction and elevated in the usual manner.

Normally, the hinged portion is tied to the main portion of the splint by a piece of string so that the foot projects through the main portion and both portions are in the same plane.

The knee-joint can now be flexed to about 45–50 degrees by simply untying the piece of string and allowing the hinged portion to move slowly and evenly downwards and the traction weights need not be removed or the leg moved in any other way. It is possible to get further flexion by using a bed with a "cut-away" side. This method proved satisfactory in operation and the proper alignment of the fractured femur was not interfered with.

Section of Orthopædics

Injuries of the Cervical Vertebræ

PRESIDENT'S ADDRESS

By V. H. Ellis, F.R.C.S.

It is a little more than six years since this subject was most ably discussed before this Society by Eastwood and Jefferson (*Proc. R. Soc. Med.*, 33, 651), but there is still much to be learnt about these injuries, and my experience of the last four years has at any rate taught me a great deal both of the details of management and the progress of the injuries.

There have been references to these injuries in medical literature from 2500 B.C. increasing to a vast quantity in recent years, and I do not propose to review them.

Serious injuries of the cervical spine must always carry a fair mortality, but the decrease in fatal bilateral dislocation from 92·6% in 1869 (Blasius) and 30% in 1930 (Langsworthy) to about 16% in my cases, suggests, unless the series are incomparable, that treatment is still improving, as it is unlikely the injuries are decreasing in severity.

The commonest causes are stated to be motor-car accidents, diving into shallow water and falling downstairs, and my cases confirm this. I have no experience of wounds or compound fractures in this region.

These injuries are usually divided into fractures, fracture-dislocations and dislocations, but with the exception of special types such as fracture of the odontoid, the neural arch or spine, this classification is not of great assistance.

I have had one example of fracture of the arch of the atlas. The mechanism by which this was produced is not clear, but it was apparently a combination of compression and extension, so that the occiput was forced downwards and backwards upon the axis. There was a minor degree of displacement and no evidence of damage to the central nervous system. The patient had severe and persistent pain in the area supplied by the small occipital nerve. The pain was immediately relieved by injecting novocain at the point where the nerve crosses the arch of the atlas, but it tended to recur.

Fractures of the odontoid process are not very uncommon. Those which are displaced are often, but not always, fatal. Fractures without displacement are difficult to diagnose because the bony fusion between the peg and body of the axis is not always complete and so simulates a fracture of the base of the process.

I recall two interesting fractures of the odontoid process with displacement. The first was demonstrated at Lambeth Hospital some years ago.

An old man was admitted to the hospital with retention of urine. When his prostate was examined it was found to be of normal size and on closer inquiry into the history the surgeon found that retention had occurred only on those occasions when the patient had fallen asleep in his chair in front of the fire. He had extensor plantar responses.

There was a history of a fall with acute flexion of the head some time previously, and an X-ray showed gross displacement of the atlas and odontoid process.

outlook of the individual is discussed. It may also be that he is specially interested in some of the snags of an accident service, such as suspected ruptures of the supraspinatus tendon, the condition known as frozen shoulder, or even low back pain.

The ideas I have roughed out apply to what appear to be straighforward cases and I will not confuse the issue by discussing the management of nerve injuries or other complications.

A word on Rehabilitation Centres. During the war these have fully proved their value in the management of bulk casualties. I am not sure of the degree to which they can be usefully employed in normal civil life. I think that in a well-established accident clinic most cases of injury can be seen through to full recovery by the team primarily responsible for their treatment. "Passing the buck", however, is always popular and sometimes it benefits the patient. Certainly the final tuning up after major injuries is best conducted in fair-sized classes, but God forfend the time when everyone who sustains a fracture thinks he cannot return to work till he has passed through a rehabilitation centre.

Dr. John H. Crosland : I would like to outline a few methods as to how we, as physical medicine specialists, can assist the orthopædic surgeon to attain the common aim of the fullest possible restoration of function to the patient.

A large number of orthopædic patients are perfectly healthy individuals leading a normal active life until they are knocked down by a bus, or sustain some similar damage. Many of these may be kept in bed for months and, during this time, unless they are helped, they more or less rapidly deteriorate both physically and mentally. It is obvious that such deterioration will also retard recovery of the actually traumatized part. In order to prevent this, the patient should be visited daily by a competent physiotherapist, and every part of his body except that immobilized by the surgeon, or that which when moved will interfere with such immobilization, should be given a full range of active movement. Breathing exercises and active contractions of abdominal and back muscles are all very important and can be given very adequately in the prone position.

Perhaps the cases requiring the most constant and patient treatment of this type are those condemned for a year or more to a plaster bed. Yet all that work is well rewarded when it is time for the patient to get up and it is seen how quickly he walks normally and how relatively good his general muscle tone can be.

I will pass rapidly over such small but important points as leaving a window over the knee-joint in a full-length leg plaster so that the patella can be passively moved twice daily; or, as advocated by some, of leaving another window in such a plaster over the quadriceps so that faradic stimulation may be given, or of leaving adequate room in a plaster so that full toe movements can be given, and come to one of the biggest bugbears. I refer to the stiff knee-joint following prolonged extension of a fractured shaft of femur in a Thomas's splint.

Generally speaking, the earlier a joint can be moved, the less likely is it to become stiff and so I propose to outline a method used to move knee-joints adopted by the orthopædic surgeon at Ashbridge E.M.S. Hospital. The idea is that the leg below the knee shall rest on the hinged extension portion of the Thomas's splint, and skin traction be applied in the normal way with the cord bearing the weight passing over a pulley at the end of the bed. The splint itself must be wide enough for the patient's foot and the hinged portion to pass inside it ; it is fixed in abduction and elevated in the usual manner.

Normally, the hinged portion is tied to the main portion of the splint by a piece of string so that the foot projects through the main portion and both portions are in the same plane.

The knee-joint can now be flexed to about 45–50 degrees by simply untying the piece of string and allowing the hinged portion to move slowly and evenly downwards and the traction weights need not be removed or the leg moved in any other way. It is possible to get further flexion by using a bed with a "cut-away" side. This method proved satisfactory in operation and the proper alignment of the fractured femur was not interfered with.

A man of 33 fell downstairs and sustained a fracture dislocation of C.5-C.6 with gross displacement. He was admitted a few hours later after an unsuccessful attempt at manual reduction. He had an almost complete paralysis of both upper limbs with sensory loss of whole right arm to pin and touch and loss of touch on left. Both legs were weak, loss of abdominal reflexes, dullness to pin-prick below D.9. Skull traction up to 40 lb. was applied. Catheterization was required once only, and lower limb recovery was fairly rapid. Reduction of the dislocation was completed by manipulation under traction at thirty-six hours. Wire and graft fixation at one week.

He was allowed up with a brace at six weeks. At this time he had gross hyperæsthesia and pain in the hands, worse on the right. The right arm had not completely recovered when the brace was discarded at three months.

At nine months after injury paralysis was almost completely recovered but with some residual stiffness of the right hand.

The X-ray showed full maintenance of position of C.5-C.6 with consolidation of the graft but there was a forward displacement of C.4-C.5 without symptoms. The significance of rupture of the interspinous ligament between C.4-C.5 was not appreciated at the time of operation.

The mechanism of production of fracture dislocations is either hyperflexion or compression or a combination of these two forces. Any marked degree of compression of the vertebral body is likely to be accompanied by fracture dislocation of the articular facets.

Fractures of the facets can sometimes but not always be seen, even in good X-rays. If present they may make reduction easy but also increase the liability to redisplacement.

Typically the upper vertebræ move forward on the lower, and the displacement is often unequal on the two sides so that a peculiar asymmetry of the neck and head can be seen on clinical examination. Study of this asymmetry is important, particularly during reduction. Forward displacement is not so obvious, as it can be partially concealed by motion at the occipito-atlantoid joint, and the patient is usually lying supine.

Attention has been drawn to the frequency with which cervical injuries are missed in the presence of head injuries due to falls. This is comparable to the combined os calcis and lumbar vertebra crush, and reminds us that compression injuries often affect more than one bone and require careful examination.

The neural injury in fracture dislocation of the spine is of two kinds. The cervical cord may be bruised or crushed, and the nerve roots emerging at the site of injury may be damaged. There is therefore often an "upper motor lesion" of the trunk and lower limbs, associated with a lower motor lesion of the cervical roots. The pain of the latter is often the patient's chief complaint.

True quadriplegias are more seldom seen in hospital because high lesions are often quickly fatal. The lesion of the cord often quickly extends upwards from the bony lesion, probably owing to œdema, but possibly by vascular damage, and death is frequently accompanied by hyperpyrexia.

Total interruption of conductivity of the cord is almost always a permanent and irremediable affair, but quite extensive paraplegias may show rapid recovery, particularly if any pressure on the cord can be relieved in a few hours. It is therefore essential that these injuries be treated as extreme emergencies. My cases of partial paraplegia have not required suprapubic cystotomy as the bladder function has returned in a few hours. Catheterization is not so dangerous in a recoverable lesion—it has been required on two occasions.

When cord symptoms are absent, reduction is not so urgent, but it is important where there are symptoms of root compression. Absence or failure of reduction

This transient increase of paraplegia with forward flexion of the head was also demonstrated in another case.

A man of 57 suffered a flexion injury from a fall. He was momentarily paralysed but resumed work.

Five years later he was admitted to hospital, having had increasing difficulty in walking for eighteen months due to weakness first in the right and later in the left leg—an X-ray showed gross forward dislocation of the atlas with fracture of the odontoid. There was spasticity of the legs and lumbar puncture showed a complete fluid block with the head flexed but relieved in extension. Occipito-axial fusion was performed under skull traction. The man died seven weeks after operation from cause apparently unrelated to the neck lesion.

Fractures of spinous processes of the cervical vertebræ in my experience have been confined to those produced by muscular action; the so-called "clay-shoveller's" fracture of the seventh cervical or first dorsal spinous process.

I have not met a case in a clay shoveller, but in a member of the Women's Land Army who was not sufficiently expert with a pitchfork. The failure of the clay to leave the shovel, or in my case the sheaf to leave the fork, fractures the spine by traction on the muscles.

These fractures usually fail to unite and persistent pain often leads to prolonged disability. Early excision of the separated spinous process is apparently the best treatment.

There has been one case in this series where a fracture of the lamina complicated a fracture dislocation, but I have not seen it as an isolated lesion.

Fractures of the bodies of the cervical vertebræ are usually of the compression or flexion type, and are frequently associated with dislocation, but I have seen one vertebral body split sagittally, which must have caused a considerable extradural hæmorrhage in the spinal canal, though no neurological symptoms were discovered.

I will now consider the more common type of fracture so often associated with dislocation.

Although severe bony damage is likely to be accompanied by severe cord injury, the severity of skeletal and neural damage does not run parallel and many cases have been described of severe neural damage in the absence of gross radiological changes. In these cases it must be presumed marked displacement of vertebræ must have occurred with rupture of ligaments and intervertebral disc, but the elasticity of the tissues restores the bones to a much more nearly normal position.

Now it is the integrity of the ligaments and disc upon which the stability of the cervical spine depends. It is the loss of this integrity which leads to the recurrence of the deformity which is so common, and the difficulty of its prevention was mentioned by Eastwood.

Nicoll has shown that when the intervertebral disc is injured in fractures of the spine its collapse is inevitable, and some angulation will persist however long the spine is immobilized in an over-corrected position.

I believe that this is also true of the cervical spine and dissent from Jefferson who apparently believed that prolonged traction would restore the integrity of the disc.

There is, however, another factor in the stability of the cervical spine, and that is the interspinous ligament.

Since I first noticed it I have found that in every case of fracture dislocation on which I have operated the interspinous ligament has shown signs of severe damage, or even complete rupture, and, what is very important, the damage is not always confined to the level of the dislocation but may also occur between the spines next above, so that a late deformity may appear at that level also.

A man of 33 fell downstairs and sustained a fracture dislocation of C.5-C.6 with gross displacement. He was admitted a few hours later after an unsuccessful attempt at manual reduction. He had an almost complete paralysis of both upper limbs with sensory loss of whole right arm to pin and touch and loss of touch on left. Both legs were weak, loss of abdominal reflexes, dullness to pin-prick below D.9. Skull traction up to 40 lb. was applied. Catheterization was required once only, and lower limb recovery was fairly rapid. Reduction of the dislocation was completed by manipulation under traction at thirty-six hours. Wire and graft fixation at one week.

He was allowed up with a brace at six weeks. At this time he had gross hyperæsthesia and pain in the hands, worse on the right. The right arm had not completely recovered when the brace was discarded at three months.

At nine months after injury paralysis was almost completely recovered but with some residual stiffness of the right hand.

The X-ray showed full maintenance of position of C.5-C.6 with consolidation of the graft but there was a forward displacement of C.4-C.5 without symptoms. The significance of rupture of the interspinous ligament between C.4-C.5 was not appreciated at the time of operation.

The mechanism of production of fracture dislocations is either hyperflexion or compression or a combination of these two forces. Any marked degree of compression of the vertebral body is likely to be accompanied by fracture dislocation of the articular facets.

Fractures of the facets can sometimes but not always be seen, even in good X-rays. If present they may make reduction easy but also increase the liability to redisplacement.

Typically the upper vertebræ move forward on the lower, and the displacement is often unequal on the two sides so that a peculiar asymmetry of the neck and head can be seen on clinical examination. Study of this asymmetry is important, particularly during reduction. Forward displacement is not so obvious, as it can be partially concealed by motion at the occipito-atlantoid joint, and the patient is usually lying supine.

Attention has been drawn to the frequency with which cervical injuries are missed in the presence of head injuries due to falls. This is comparable to the combined os calcis and lumbar vertebra crush, and reminds us that compression injuries often affect more than one bone and require careful examination.

The neural injury in fracture dislocation of the spine is of two kinds. The cervical cord may be bruised or crushed, and the nerve roots emerging at the site of injury may be damaged. There is therefore often an "upper motor lesion" of the trunk and lower limbs, associated with a lower motor lesion of the cervical roots. The pain of the latter is often the patient's chief complaint.

True quadriplegias are more seldom seen in hospital because high lesions are often quickly fatal. The lesion of the cord often quickly extends upwards from the bony lesion, probably owing to œdema, but possibly by vascular damage, and death is frequently accompanied by hyperpyrexia.

Total interruption of conductivity of the cord is almost always a permanent and irremediable affair, but quite extensive paraplegias may show rapid recovery, particularly if any pressure on the cord can be relieved in a few hours. It is therefore essential that these injuries be treated as extreme emergencies. My cases of partial paraplegia have not required suprapubic cystotomy as the bladder function has returned in a few hours. Catheterization is not so dangerous in a recoverable lesion—it has been required on two occasions.

When cord symptoms are absent, reduction is not so urgent, but it is important where there are symptoms of root compression. Absence or failure of reduction leads to a permanent deformity, usually of minor degree, but the cervical spine becomes stable in a few months, the damaged ligaments being replaced by scar tissue, and there is usually a rapid outgrowth from the front of the body below the lesion which supports and stabilizes the body of the vertebra above.

Motion is very little restricted as most of the movement of the neck occurs at the upper three joints.

In the absence of neural damage, therefore, reduction is not essential if it is contra-indicated by the age or condition of the patient. Protection of the injured spine in slight extension at first by sandbags, and subsequently by some form of cervical brace until stability is restored, is all that is required.

The late onset of symptoms due to cord injury is apparently uncommon. I know of two cases following cervical injury, though whether they were due to scarring of the cord or membranes or due to the pressure of a retropulsed disc, I cannot say. Symptoms of root pain may persist or appear late, particularly in unreduced lesions, and it is possible that root pains also may be due to a herniated disc.

In my opinion all dislocations should be treated at once, unless contra-indicated by the age and condition of the patient.

Reduction of nearly all dislocations can be achieved by manipulation or traction, open reduction being very rarely required, and I have no experience of it in the cervical spine. Reduction of dislocations can frequently be effected by manipulation, though I believe it to be a moderately dangerous procedure.

A child was brought to hospital with a history of a fall into a basement area on the previous day. Its mother stated that she found it with its neck twisted and flexed and pulled it straight. This was probably a unilateral dislocation reduced by unskilled traction. There was no resulting disability.

But in another case with a fracture dislocation of C.4-C.5 with minor C.N.S. symptoms, manipulation under anæsthesia failed to reduce the dislocation but considerably increased the degree of paralysis.

The man subsequently came under my care and recovered completely following skull traction, reduction and fixation by wire and graft.

The chief objection to manipulation, however, is the extreme difficulty of retaining position subsequently. The application of a Minerva jacket under such circumstances is a formidable task, its retention by the patient an ordeal, and the liability to re-displacement very great.

A youth of 18 injured his neck playing football. He was admitted twenty-four hours later with a dislocation of C.5-C.6. No fracture was seen. He had weakness of both hands and the right leg but no bladder paralysis. There was hyperæsthesia of the hands. With skull traction 40 lb. one facet unlocked and reduction was completed by manipulation under pentothal. A Minerva plaster was applied, but three months later while still in plaster redisplacement occurred, but without symptoms (figs. 1, 2 and 3). The spine was wired and grafted in the displaced position with a good functional result.

This case convincingly showed the unreliability of plaster fixation. It was subsequently proved that wiring the spinous process, under traction, to restore stability, and fixation by graft is a much more reliable method.

Traction by other than skeletal means is almost intolerable to the patient, and in my opinion is not justifiable. Skeletal traction may be applied to the cranial vault or the zygomatic arches. The application of hooks to the latter is easy and is probably the method of choice in the absence of special apparatus.

Traction on the cranial vault can be applied by the Blackburn apparatus or by stainless steel wire passed extradurally between two burr holes on either side of the skull. In all cases requiring traction I have used the Blackburn skull tractor.

Some details of the application of this apparatus may be worth recording. The object is to fix the flanges on the screws into the diploe between the two tables of the skull. The amount of diploe is very variable and is sometimes absent, particularly in the aged and very young.

The flanges may, if necessary, be placed against the inner table, i.e. extradurally, but, if so, the apparatus is only stable if both sides of the skull are treated in the same way.

The trephine holes should be symmetrically placed about 1½ in. vertically above the external meati below the parietal eminences. Traction must be vertical in relation to the skull. I have always used local anæsthesia for making the trephine holes as being safer. The wounds are sealed with collodion gauze. The patient having been placed supine on a Pearson bed head to foot of bed, 15 lb. of traction is applied to the skull tractor over a pulley with a check string in case of slipping. The bed is tilted so that the patient's body-weight is used as counter-traction. The patient's neck is not extended, in fact it may be very slightly flexed, which seems to help in unlocking of the facets. As soon as traction is applied, minor movements of the patient's head are not dangerous and his position is not uncomfortable.

Since seeing a young woman hanging from the roof of Olympia by her teeth, I have ceased to be frightened of traction, and rapidly increase the traction to 40 lb. or so, taking lateral X-rays at short intervals to observe the progress of distraction.

With adequate traction the facets may reduce themselves, but occasionally this occurs on one side only, producing the asymmetry of the neck previously mentioned.

When this occurs, manipulative reduction is easily accomplished under pentothal without releasing the traction. Gentle rotation of the head with slight lateral flexion to the appropriate side completes the reduction, sometimes with a palpable click, and the asymmetry disappears. If an X-ray confirms reduction, traction is immediately reduced to 15 lb. to allow the facets to engage normally while maintaining stability.

Even heavy traction is surprisingly painless and 15 lb. fairly comfortable. I have known unilateral subluxation where the facets were poised tip on tip, in which reduction occurred spontaneously with an audible snap under morphia without traction. Such an event cannot, of course, occur with a full dislocation.

Reduction having been accomplished, the next stage is to restore stability to the spine. Prolonged recumbency is tedious and uncertain. Immobilization in plaster is uncomfortable, difficult and insecure. Operative fixation is relatively easy, certain, and more satisfactory to the patient.

The patient, still under 15 lb. of traction, is transferred to the theatre and anæsthetized with an endotracheal tube, and placed in a prone position with his head supported on a rest.

The area having been prepared, the two vertebræ above and below the injury are exposed by a mid-line incision. The area is vascular, and a drip transfusion of a pint of blood may be advantageous.

On exposure one or more interspinous ligaments will be seen damaged. Abnormal mobility may be recognized at the site of the lesion which may also be located by identifying the spinous processes from the large and easily recognizable axis, or by a lateral X-ray with a metal marker on one of the spines. A stainless steel wire on an aneurysm needle is now passed beneath an undamaged interspinous ligament round a spine above the lesion and back caudal to a spine below the lesion, and the two ends are then tied at the side. As the wire is tightened, the head traction is released.

This replacement of the interspinous ligament by wire immediately produces a marked increase in the stability of the spine, and allows the rest of the operation to be conducted with safety.

One word of warning—the spinous process of the third cervical vertebra is a miserable thing, and it is better to put a wire round the spine of the axis than to trust to it (figs. 4, 5 and 6).

leads to a permanent deformity, usually of minor degree, but the cervical spine becomes stable in a few months, the damaged ligaments being replaced by scar tissue, and there is usually a rapid outgrowth from the front of the body below the lesion which supports and stabilizes the body of the vertebra above.

Motion is very little restricted as most of the movement of the neck occurs at the upper three joints.

In the absence of neural damage, therefore, reduction is not essential if it is contra-indicated by the age or condition of the patient. Protection of the injured spine in slight extension at first by sandbags, and subsequently by some form of cervical brace until stability is restored, is all that is required.

The late onset of symptoms due to cord injury is apparently uncommon. I know of two cases following cervical injury, though whether they were due to scarring of the cord or membranes or due to the pressure of a retropulsed disc, I cannot say. Symptoms of root pain may persist or appear late, particularly in unreduced lesions, and it is possible that root pains also may be due to a herniated disc.

In my opinion all dislocations should be treated at once, unless contra-indicated by the age and condition of the patient.

Reduction of nearly all dislocations can be achieved by manipulation or traction, open reduction being very rarely required, and I have no experience of it in the cervical spine. Reduction of dislocations can frequently be effected by manipulation, though I believe it to be a moderately dangerous procedure.

A child was brought to hospital with a history of a fall into a basement area on the previous day. Its mother stated that she found it with its neck twisted and flexed and pulled it straight. This was probably a unilateral dislocation reduced by unskilled traction. There was no resulting disability.

But in another case with a fracture dislocation of C.4-C.5 with minor C.N.S. symptoms, manipulation under anæsthesia failed to reduce the dislocation but considerably increased the degree of paralysis.

The man subsequently came under my care and recovered completely following skull traction, reduction and fixation by wire and graft.

The chief objection to manipulation, however, is the extreme difficulty of retaining position subsequently. The application of a Minerva jacket under such circumstances is a formidable task, its retention by the patient an ordeal, and the liability to re-displacement very great.

A youth of 18 injured his neck playing football. He was admitted twenty-four hours later with a dislocation of C.5-C.6. No fracture was seen. He had weakness of both hands and the right leg but no bladder paralysis. There was hyperæsthesia of the hands. With skull traction 40 lb. one facet unlocked and reduction was completed by manipulation under pentothal. A Minerva plaster was applied, but three months later while still in plaster redisplacement occurred, but without symptoms (figs. 1, 2 and 3). The spine was wired and grafted in the displaced position with a good functional result.

This case convincingly showed the unreliability of plaster fixation. It was subsequently proved that wiring the spinous process, under traction, to restore stability, and fixation by graft is a much more reliable method.

Traction by other than skeletal means is almost intolerable to the patient, and in my opinion is not justifiable. Skeletal traction may be applied to the cranial vault or the zygomatic arches. The application of hooks to the latter is easy and is probably the method of choice in the absence of special apparatus.

Traction on the cranial vault can be applied by the Blackburn apparatus or by stainless steel wire passed extradurally between two burr holes on either side of the skull. In all cases requiring traction I have used the Blackburn skull tractor.

Two laminæ above and below the lesion on either side are now roughened with an electric burr and two tibial grafts of equal and appropriate length with holes drilled near their ends are fixed in position with a wire in a somewhat similar manner to the first wire. Secure fixation is easily attained, the grafts lying under the overhanging bifid spines (figs. 7 and 8).

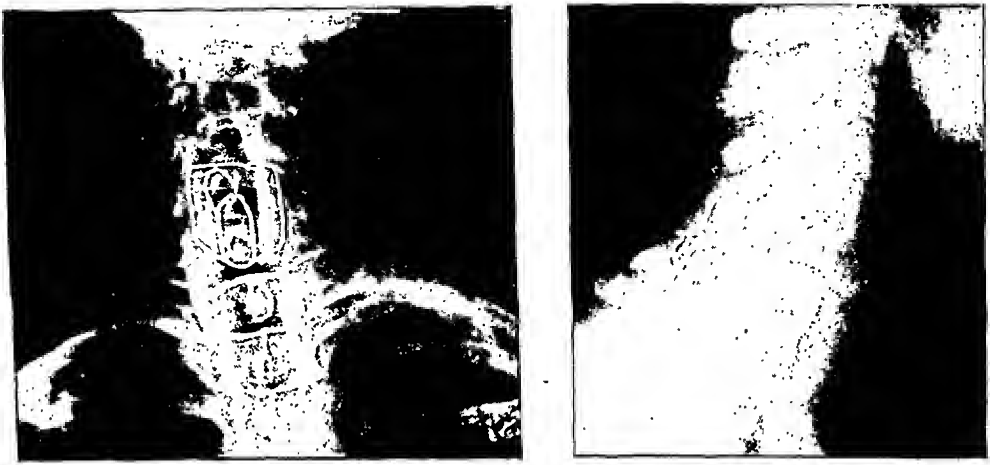

FIG. 7. FIG. 8.

FIGS. 7 and 8.—Stainless steel wire round spinous processes replacing damaged interspinous ligament and restoring stability. Two tibial grafts wired into position.

The wound is now closed and the skull tractor removed. The patient is kept supine in bed for two to three weeks and then fitted with a cervical brace and allowed up. The brace is retained for three months, by which time the X-ray usually shows consolidation of the grafts (figs. 9 and 10).

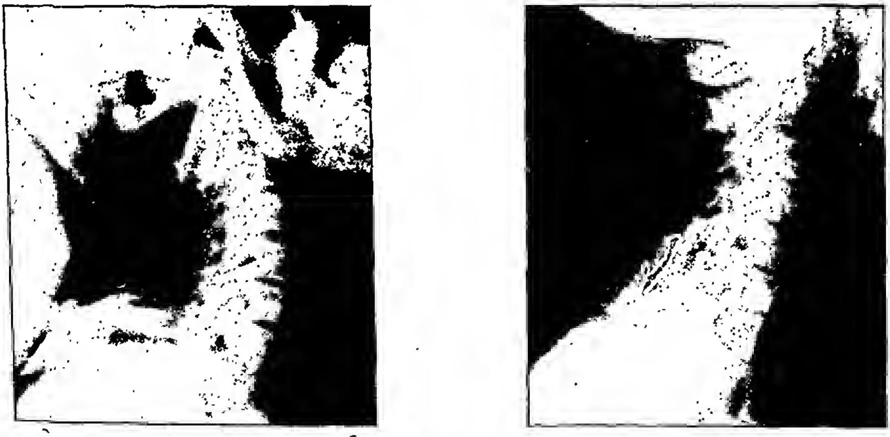

FIG. 9. FIG. 10.

FIGS. 9 and 10.—Consolidation of grafts after six months.

By this method the patient is not confined to bed for more than a month, no massive plaster jacket is required, and the danger of redisplacement is minimized. Very little

Protein Metabolism in Relation to Disease

PRESIDENT'S ADDRESS

By Professor H. P. Himsworth, M.D.

Although only some twenty-two amino-acids are available for the construction of all varieties of protein, no two proteins are alike. Not only do those of the different tissues differ from each other but there are subtle species differences between the proteins of the same organ. The tissue differences can be referred, at least in part, to differences in their amino-acid composition; those of the skin, for example, being particularly rich in cystine, those of the wheat germ in glutamic acid. In one instance a species difference has been referred to a similar difference in composition, it having been found that cows' milk contains more arginine, tryptophan and sulphur-containing amino-acids than human milk (Williamson, 1944). But, as yet, most species differences are too subtle for detection by chemical analysis and recourse must be had to immunological tests. It would, however, be unjustifiable to assume that all differences between proteins are referable either to the proportions or arrangement of the various amino-acids within the molecule. The classical researches on the pneumococcal antigens have clearly shown that the protein moiety is common to all these and that the specificity of the different types is dependent upon a characteristic polysaccharide. More recently lipoproteins have been distinguished (Cohn *et al.*, 1944), and it may well be that, with the development of more delicate methods of separating proteins, species, and perhaps even tissue, differences dependent upon such attached substances may be revealed. Nevertheless the myriads of different proteins formed in Nature are each characteristic and remain true to type. Alterations in the quantity or quality of the dietary protein may influence the amount of the different tissue proteins formed, but they will not apparently induce the body to form imperfect or unusual protein molecules.

This well-established specificity of the different tissue proteins has very naturally led to the tacit assumption that the proteins in the tissues are in a comparatively stable state and to be regarded more as structural elements than as participants in the stream of metabolism on the same plane of activity as carbohydrates and fats. Against the background of this view Folin put forward the conception of endogenous and exogenous metabolism. According to this endogenous protein metabolism was the result of the breakdown through wear and tear of the actual tissues of the body. Exogenous protein metabolism, on the other hand, represented the burning off of the excess of the amino-acids, derived from the dietary protein, after the tissues had abstracted those required for their repair. These views now appear to be mistaken. Far from being stable structures the proteins of the different tissues are constantly undergoing rapid change. Amino-acids pass from one protein molecule to another not only in the same, but between different tissues. Individual amino-acids are constantly being broken down and the fragments built up either into similar or different amino-acids. When protein is ingested the resulting amino-acids are swept into this whirl of activity and can in no way be distinguished, either by situation or stability, from those already present in the tissues (Schoenheimer, 1942). The limitation of motion has followed in any case, and at least two are serving in the Army, Category A.

The third stage of treatment is really only necessary in those cases which have had neural symptoms. As already mentioned, the incomplete paraplegia rapidly recovers and no disability in the legs remains after a month or so of exercises.

The recovery from root symptoms in the arms is often much more difficult. The severe pain and hyperæsthesia in the arms makes the task of the physiotherapist in restoring the wasted muscles difficult, and it is very unpleasant for the patient. It may be very difficult to prevent the finger-joints from becoming stiff if the patient cannot bear to be touched. Fortunately, the nerve lesion is usually a neurapraxia, and recovers rapidly but in one of our cases a minor permanent weakness persists.

FRACTURE DISLOCATIONS OF THE CERVICAL SPINE.

Plan of Treatment in Early Cases of Unreduced Dislocations.

(1) Skull traction using Blackburn skull tractor. Local anæsthetic. Suprapubic cystostomy at the same time if required.

(2) Traction increased as necessary up to 40 lb. in course of twenty-four to forty-eight hours on reversed Pearson bed. Frequent check lateral X-rays.

(3) If unreduced by traction manipulate under pentothal in bed on traction. (Done in 3 unilateral cases.)

(4) At seven to ten days wire and graft cervical spine above and below lesion Localizing X-ray. Traction continuing until wires are tightened.

(5) Bed with head between sandbags for three weeks.

(6) Up wearing cervical brace for three to four months.

FRACTURE DISLOCATIONS CERVICAL SPINE.

Total number of cervical spine injuries	34
Number of fracture dislocations	20

Average age 37. Oldest 65. Youngest 16.

soldiers, when many races subsist on much smaller amounts. Long ago Chittenden maintained that intakes of ¼ to ⅓ gramme of protein per kilo sufficed for adults and certainly limitation of dietary protein short of starvation does not bring growth to a standstill or prevent the inception of lactation or the production of an apparently normal fœtus. The question, however, is one not of absolute adequacy or inadequacy, but of optimal or suboptimal nutrition. Comparison of races living on high with those living on low protein diets reveals that the former have better physique, more energy and better health than the latter (Cuthbertson, 1940). Recent studies in Holland have shown that when the supply of protein is minimal, lactation can be established, and milk of normal composition obtained, but lactation cannot be maintained. Observation in the East on races taking low protein diets revealed that, while the diet appeared adequate under ordinary conditions, additional strain such as pregnancy (Upadhyay, 1944) or infection, precipitated illnesses which either did not occur, or appeared only in a mild form, in races taking larger amounts of dietary protein.

Therefore, although under ordinary circumstances gross restrictions of dietary protein are necessary to produce illness, much lighter restrictions may allow such illnesses to appear under strain. Such strains are growth, pregnancy, infection, injury and surgical operations. Both physicians and surgeons would do well to bear this in mind when devising pre-operative treatment or supportive measures.

Biologically speaking the individual amino-acids fall into two groups according to whether they must or need not, be supplied in the diet. These groups are called respectively the essential and the non-essential amino-acids. There is a possibility of a misconception arising from this terminology. By the use of tracer elements it has been shown that all the amino-acids, with the possible exception of lysine, can be synthesized within the body, either from the chemical groupings in other amino-acids or from simpler materials (Schoenheimer, 1942). Apparently, however, the rate of production of ten of the amino-acids is too slow for the needs of the body so that, if normal nutrition is to be maintained, supplementary quantities must be supplied in the food. These have, therefore, come to be regarded as the essential amino-acids but it would be quite unjustifiable to regard the remaining dozen or so of such acids as optional substances which may or may not be incorporated in the body proteins. It may well be that in the future we shall discover conditions in which the demand for an amino-acid, now considered unessential, outstrips its production. Under such circumstances, that amino-acid would be upgraded to the essential category. It is not even certain that all those amino-acids now called essential are always so. Their reputation as such is largely based upon their being necessary for growth and for this threonine, tryptophan, methionine, leucine, isoleucine, valine, lysine, phenylalanine, histidine and arginine are indispensable (Rose, 1938). But only the first six appear necessary for the maintenance of the adult rat and phenylalanine can be replaced by tyrosine (Burroughs, Burroughs and Mitchell, 1940; Mitchell, 1942). These findings have been confirmed for human adults (Rose *et al.*, 1943), and the indispensability of methionine, threonine, isoleucine and leucine established. There is even evidence that, in protein-depleted men, administration of the ten amino-acids will promote the formation of more protein than intact protein itself (Emerson and Binkley, 1946). The quantitative requirements of healthy men for the different amino-acids have not yet been ascertained but data are available on the approximate amounts of twelve of these in a diet adequate to maintain health (Melnick, 1943). It is evident, however, that the requirements differ both qualitatively and quantitatively, at the various stages of development.

Closely connected with the question of essential amino-acids is the conception of "key" amino-acids. When an essential amino-acid is removed from the diet then breakdown of protein is accelerated so that more nitrogen is excreted in the urine proteins of the body are boiling with activity yet their characteristics and the structure of the tissues they compose, are preserved in a dynamic equilibrium. Astounding as is this new view it does indicate the explanation of one problem, namely that of "labile body protein".

It has long been known that when a starved animal is fed it retains a significant proportion of the ingested protein and that, on starving the animal again, protein to the amount retained is broken down. Under the old view of endogenous and exogenous protein metabolism such protein should have been stored, just like fat in adipose tissue or glucose as glycogen. But no such stores could ever be demonstrated. All that could be seen was that certain cells, such as the liver parenchyma, enlarged on repletion and shrank on starvation. But their chemical composition as regards protein remained the same. According to the new view the amino-acids from ingested protein are incorporated into the tissues as components of the characteristic proteins of the body. The mass of living protoplasm in the body thus becomes adjusted to the intake of protein. Decrease this and the tissues of the body itself, not hypothetical stores of protein, begin to waste. That is the significance of a nitrogen excretion greater than the intake; that is why such a negative nitrogen balance in illness cannot lightly be dismissed.

REQUIREMENTS FOR PROTEIN AND AMINO-ACIDS

A distinction must be drawn between the requirements for a particular protein, when this constitutes the sole or main source of amino-acids, and the requirements for the mixture of proteins in a normal diet. The former is dependent upon the amino-acid composition of the particular protein and is of practical importance only when the protein intake is low either because of illness or shortage of dietary protein. The requirement for mixed protein is, in health and with normal food supplies, largely independent of such considerations for differences in the amino-acid composition of the numerous proteins in a normal diet compensate each other so that the mixture as a whole has an adequate biological value (Macrae, Henry and Kon, 1943). It is, therefore, possible to consider separately the requirements for proteins in general and the requirements for individual amino-acids in particular.

The requirements for protein in general have largely been determined in reference to growth and the maintenance of weight, and the conclusions drawn from such studies are only valid when considered in relation to the intake of other dietary substances. When protein is the sole food it has to provide not only material for the construction of body tissues but also fuel for their working. Under such conditions the amounts required to promote growth or maintain weight are necessarily large. But, when the diet contains other adequate sources of fuel, ingested protein can largely be devoted to its proper purpose, and of such energy foods carbohydrate is the most efficient "protein sparer" (Lusk, 1917). This point becomes important when, as in illness, the food intake is low and it is necessary to obtain the maximum benefit from the limited intake of protein which is possible. In ordinary circumstances, however, it can largely be disregarded for, when food supplies are adequate, the natural choice ensures a dietary comprising adequate amounts of energy foods. Then the special problems of protein requirements in health are reduced to determining the extra requirements for growth, pregnancy and lactation. Taking the requirements for adults as the standard the consensus of opinion is that this is of the order of 1 gramme of protein per kilo of body-weight daily. In children, however, 3 grammes/kilo is necessary and intermediate amounts in pregnancy and lactation (McCollum, Orent-Keiles and Day, 1939). Details of these different requirements are given in the Table constructed by Cuthbertson (1944) from the most recent figures on the subject.

It may well be asked what is the justification for such liberal allowances of protien, and the even higher intakes sanctioned by tradition for such special categories as soldiers, when many races subsist on much smaller amounts. Long ago Chittenden maintained that intakes of ¼ to ⅓ gramme of protein per kilo sufficed for adults and certainly limitation of dietary protein short of starvation does not bring growth to a standstill or prevent the inception of lactation or the production of an apparently normal fœtus. The question, however, is one not of absolute adequacy or inadequacy, but of optimal or suboptimal nutrition. Comparison of races living on high with those living on low protein diets reveals that the former have better physique, more energy and better health than the latter (Cuthbertson, 1940). Recent studies in Holland have shown that when the supply of protein is minimal, lactation can be established, and milk of normal composition obtained, but lactation cannot be maintained. Observation in the East on races taking low protein diets revealed that, while the diet appeared adequate under ordinary conditions, additional strain such as pregnancy (Upadhyay, 1944) or infection, precipitated illnesses which either did not occur, or appeared only in a mild form, in races taking larger amounts of dietary protein.

Therefore, although under ordinary circumstances gross restrictions of dietary protein are necessary to produce illness, much lighter restrictions may allow such illnesses to appear under strain. Such strains are growth, pregnancy, infection, injury and surgical operations. Both physicians and surgeons would do well to bear this in mind when devising pre-operative treatment or supportive measures.

Biologically speaking the individual amino-acids fall into two groups according to whether they must or need not, be supplied in the diet. These groups are called respectively the essential and the non-essential amino-acids. There is a possibility of a misconception arising from this terminology. By the use of tracer elements it has been shown that all the amino-acids, with the possible exception of lysine, can be synthesized within the body, either from the chemical groupings in other amino-acids or from simpler materials (Schoenheimer, 1942). Apparently, however, the rate of production of ten of the amino-acids is too slow for the needs of the body so that, if normal nutrition is to be maintained, supplementary quantities must be supplied in the food. These have, therefore, come to be regarded as the essential amino-acids but it would be quite unjustifiable to regard the remaining dozen or so of such acids as optional substances which may or may not be incorporated in the body proteins. It may well be that in the future we shall discover conditions in which the demand for an amino-acid, now considered unessential, outstrips its production. Under such circumstances, that amino-acid would be upgraded to the essential category. It is not even certain that all those amino-acids now called essential are always so. Their reputation as such is largely based upon their being necessary for growth and for this threonine, tryptophan, methionine, leucine, isoleucine, valine, lysine, phenylalanine, histidine and arginine are indispensable (Rose, 1938). But only the first six appear necessary for the maintenance of the adult rat and phenylalanine can be replaced by tyrosine (Burroughs, Burroughs and Mitchell, 1940; Mitchell, 1942). These findings have been confirmed for human adults (Rose *et al.*, 1943), and the indispensability of methionine, threonine, isoleucine and leucine established. There is even evidence that, in protein-depleted men, administration of the ten amino-acids will promote the formation of more protein than intact protein itself (Emerson and Binkley, 1946). The quantitative requirements of healthy men for the different amino-acids have not yet been ascertained but data are available on the approximate amounts of twelve of these in a diet adequate to maintain health (Melnick, 1943). It is evident, however, that the requirements differ both qualitatively and quantitatively, at the various stages of development.

Closely connected with the question of essential amino-acids is the conception of "key" amino-acids. When an essential amino-acid is removed from the diet then breakdown of protein is accelerated so that more nitrogen is excreted in the urine than is ingested in the food. Certain proportions of all the amino-acids are required in the construction of most tissue proteins. If one is missing the protein cannot be constructed and the remaining amino-acids are rapidly burnt off. The missing amino-acid is thus in the position of a limiting factor, a "key" component, in protein synthesis and wastage will continue until it is supplied in sufficient amounts.

THE PRODUCTION OF PROTEIN DEFICIENCY

Deficiency states occur when the demand for a nutrient exceeds its supply. It is thus possible to produce protein deficiency either by curtailing the amount of protein entering the body or, such amounts being normal, by increasing its utilization or loss from the body. Theoretically supplies may be restricted because of inadequate diet or conditions of the alimentary tract such as anorexia, failure of digestion or absorption. Excessive utilization occurs in pregnancy, fevers, in metabolic diseases like diabetes mellitus, and after injury or operation; excessive loss in renal lesions or conditions, such as burns, where body fluids escape.

Dietary deficiency confined to protein does not ordinarily occur in Western civilizations for, with remarkable regularity, the dietary habits of such countries ensure that, whatever the calory value of the diet, protein supplies 10 to 12% of the calories. It is not so elsewhere. Many Eastern races take diets containing less than the minimum of protein and live habitually in a state which in Europe is only seen in times of famine. Under these circumstances the order of development of the clinical states referable to dietary deficiencies is largely determined by the ability of the body to store different foodstuffs. Energy foods can be stored in quantity; protein and most vitamins to only a limited extent. In famine, therefore, protein deficiency, with or without vitamin deficiencies, dominates the clinical picture.

Under normal conditions in Western civilizations protein deficiency states usually occur secondary to some illness. This may be a structural lesion of the alimentary tract, such as a carcinoma of the œsophagus, which bars access of food to the gut; a gastro-colic fistula, which short circuits food past the small intestine; or an operative procedure on the gut itself. On the other hand, the illness may be a disturbance of function.

Anorexia is a common cause of latent, and more rarely of manifest, protein deficiency. It may arise from mental causes, as in anorexia nervosa, or lesions in the alimentary tract such as alcoholic gastritis. But it has only recently been realized that protein deficiency itself produces anorexia and that this is related to the absence of particular amino-acids. Thus, in the absence of methionine the food intake of rats falls to very low levels. Addition of a few milligrammes of this substance restores the appetite to normal although the amount in the diet is still insufficient to meet other requirements. The addition of the other sulphur-containing amino-acid, cystine, is, however, of no benefit (Glynn, Himsworth and Neuberger, 1945). A vicious cycle is thus set up by anorexia and this may explain the disappearance of appetite on starvation and the common clinical observation that, once a case of anorexia nervosa has been forced to eat, appetite may rapidly return.

Failure to digest dietary protein into amino-acids would, if it occurred, be a potent cause of protein deficiency and according to tradition such a failure occurs in extreme starvation. But little evidence in support of this view has been obtained in modern studies on starvation. What has been obtained, however, is evidence that absorption of amino-acids from the gut is retarded in starved patients who suffer also from diarrhœa. At Belsen camp there were many such patients and hydrolysed casein given to them by mouth passed through the gut and appeared as a solution of amino-acids in the diarrhœic stools (Dent, Pitt-Rivers and Vaughan, 1945). It cannot, therefore, be assumed that benefit will accrue from the oral administration of pre-digested protein to cases of diarrhœa and, indeed, observations on the above patients suggest that the preparations then available had no advantage over skim milk powder. It is, however, likely that in profuse small intestinal diarrhœa, such as occurs in typhoid fever or regional ileitis, much ingested protein may be lost and parenteral administration of suitable protein may be the only effective way of restoring the nutrition of such cases.

Specific amino-acid deficiencies can rarely, if ever, arise from a general shortage of protein, whether produced directly or indirectly. They may, however, arise secondary to other causes. A poison may react with a particular amino-acid, producing a substance inutilizable in metabolism, and thus lead to a conditioned amino-acid deficiency.

HYPOPROTEINÆMIA

The maintenance of a normal level of protein in the plasma requires the ingestion of adequate dietary protein. Not all protein foods are equally useful (Madden and Whipple, 1940; Whipple, 1942). Beef serum is five times as effective as beef stomach and there is some evidence that, under certain conditions, sulphur-containing amino-acids occupy a key position in the synthetic process (Whipple, 1942; Glynn, Himsworth and Neuberger, 1945). Plasma albumin, together with the two globulins, fibrinogen and prothrombin, are apparently formed in the liver. The source of the remaining plasma globulins is not certain but the association of hyperglobulinæmia with proliferation of the reticulo-endothelial system suggests that they may originate in that tissue. Arising from different sources, and varying so independently in disease, there would seem to be as little theoretical justification as there is clinical value in the common practice of expressing the state of the plasma proteins by the albumin-globulin ratio.

Of the plasma proteins albumin is most susceptible to abnormal conditions. In starvation, either direct or indirect, it falls relatively quickly while plasma globulin is affected little if at all. Owing to the small size of its molecule it readily escapes from the blood when capillary permeability is increased as happens in the renal glomerulus in nephritis. It is apparently synthesized more slowly than the globulins and even mild liver damage is sufficient to retard this synthesis. But despite the different origin of albumins and most globulins the levels of one in the plasma is not without influence on the other. If the protein intake is satisfactory, yet hypo-albuminæmia develops either from loss or deficient synthesis, then slowly the plasma globulin concentration increases until the total concentration of protein in the plasma may equal, or even surpass, the normal level. The reason for this increase is not clear but it, at least, serves a useful purpose in raising the reduced colloidal osmotic tension of the blood.

Œdema is the most striking objective manifestation of hypoproteinæmia, and commonly appears when the total plasma protein level falls below 4·5 to 5 grammes/100 c.c. It is, however, more closely correlated with the albumin fraction and this is to be expected as albumin contributes most to the colloidal osmotic tension of the blood. Whether the fall is produced by deficient formation, as in starvation and liver disease, or by depletion, as in nephrosis or exudation, if the plasma albumin falls below 3 grammes/100 c.c. œdema appears (Bruckman and Peters, 1930) only to disappear when the level is restored by transfusion of albumin (Thorn, Armstrong and Davenport, 1946). Hypoproteinæmia, however, only predisposes to œdema. Adequate amounts of water and salt are required for its formation. Dehydration, therefore, from any cause may prevent its development so that œdema may only appear in the course of treatment when fluid is restored to the body. This has been a common experience in the treatment of hunger œdema complicated by dysentery and, in civil practice, accounts for the œdema which may develop in wasted diabetics after the polyuria is controlled by insulin. It is, however, doubtful whether all cases of famine œdema can be explained on these lines. Some can (Leyton, 1946) and hypoproteinæmia probably plays its part in most. But under conditions of famine other deficiencies are present and indications have been obtained that these may introduce another factor, probably that of increased capillary permeability (Keys, Taylor, Mickelsen and Henschel, 1946).

The plasma proteins occupy a peculiarly important position in relation to protein metabolism for their level in the blood depends upon the protein content of the body tissues in general. It is a common clinical observation that, when blood transfusions of ordinary size are given to hypoproteinæmic patients, the added plasma proteins rapidly leave the circulation although the blood corpuscles remain behind. Considerable light has been thrown upon the significance of this phenomenon by experiments upon dogs made hypoproteinæmic by dietary deficiency. These showed that 30 grammes of albumin had to be retained in the body to secure an increase of 1 gramme in the circulation, and conversely that to lower the total circulating albumin by 1 gramme the body had to be depleted of 30 grammes (Sachar, Horvitz and Elman, 1942). Evidently an equilibrium is maintained between plasma albumin and tissue protein and that this has a nutritional significance is shown by the observation that it is possible to keep dogs in nitrogen equilibrium when transfusions of plasma are the sole source of protein. Applying these results to a man of average size it will be seen that a fall in plasma albumin concentration of 1 gramme/100 c.c. implies a loss of protein to the body of over 1 kilo, the amount contained 4 kilo of muscle. A fall of plasma albumin concentration should not, therefore, be regarded lightly for in all cases it is diagnostic of a far greater depletion of body protein.

INJURY, FEVER AND CONVALESCENCE

In febrile illnesses there is an excessive breakdown of body protein. Associated with this is a raised basal metabolic rate (Du Bois, 1936). The destruction of protein is due neither to the raised metabolism nor to the fever for the protein breakdown in fever is greater than in normal subjects whose metabolism has been elevated to the same degree by exercise (Kocher, 1914), and is not augmented in pyrexias induced by external temperature (Graham and Poulton, 1912-13). It is apparently referable to some unknown process initiated by the illness itself which has been loosely termed "toxic destruction". If this term is taken to imply a process due to an extrinsic toxin it is probably a misnomer for Cuthbertson (1928) has demonstrated that a similar destruction and elevation of the metabolic rate occurs after injury even when this is of a relatively minor character. This finding has been confirmed after fractures, dislocations, burns and surgical operations (Cuthbertson, 1945) and it now seems evident that the process is a reaction of the body itself. The sequence of events seems to be the same in each case but can be studied in its simplest form after a single injury. Shortly after injury the nitrogen breakdown begins to increase and reaches its maximum on the second to eighth day. It then sinks back to normal in a week or ten days and thereafter the phase of convalescence follows which may last for several weeks, and in which more protein is stored than is destroyed. Finally the body again comes into nitrogen equilibrium and excretion equals intake.

The relationship of dietary protein to this train of events is of importance. In the stage of active breakdown the loss can be mitigated by increasing the intake of protein but it can rarely be prevented entirely even by enormous amounts of dietary protein. As the rate of breakdown diminishes, however, it becomes correspondingly easy to promote retention of protein by augmenting the intake and, in the convalescent phase, the deficit may be rapidly replaced, and the duration of this phase shortened, by dietary measures. The degree of protein breakdown is influenced by two further factors. It is increased when atrophy consequent upon inactivity is allowed to occur; when the previous nutrition is poor it may be absent.

The significance of this reaction is not yet clear. The excessive excretion of nitrogen in the first ten days after a simple fracture may be equivalent to 8% of the total body protein, that is about four times the total protein content of the liver. If this large loss were a local event, confined to the region of the injury, it could not escape detection. The excessive protein destruction seems to involve the body tissues as a whole and the associated excessive excretions of phosphorus and sulphur indicate that it is largely derived from muscle. Cuthbertson (1932) has suggested that the purpose of this generalized breakdown of body protein is to provide large amounts of amino-acids necessary for repair, and so render the healing process independent of the intake of dietary protein. Implicit in this suggestion is the idea that certain key amino-acids are in great demand and that the excessive excretion of nitrogen arises from the destruction of the excess of other amino-acids which are less urgently required in the repair process but which are simultaneously released when body protein is broken down. In support of this suggestion is the observation that dietary supplements of methionine reduce conspicuously the excretion of nitrogen following experimental burns (Croft and Peters, 1945). Of the mechanism initiating such protein destruction there is no certain knowledge. That it can be influenced by endocrine factors has been shown (Cuthbertson, Shaw and Young, 1941; Josiah Macy Foundation Report, 1942), but that these are responsible for the actual event has not been established.

The practical importance of these observations has not yet been fully realized. It seems probable that loss of body proteins is responsible for the wasting and cachexia, termed "wound phthisis" (Rusakow, 1943) which follows infected injuries. It may well underlie the "toxic anæmia" of chronic infections and those following burns. It may be the reason why Eastern troops, on low protein diets, as compared with white troops on adequate protein diets, show more physical deterioration, more complications like anæmia and require protracted convalescence, after injury or infection. These points require further investigation but the immediate practical indications are clear. Before operation any depletion of the protein stores of the body should be remedied. In the acute stage of short illnesses, or for the first few post-operative days, the intake of protein should be maintained at reasonable levels but, as most will be destroyed, metabolism need not be overloaded by forcing it to high levels. In protracted illnesses, however, every gramme of protein prevented from destruction counts and the protein intake should be maintained if necessary by parenteral feeding. But as soon as improvement appears the level of intake should be forced up and thereafter, and throughout convalescence, should not fall below 150 grammes daily. Statistical evidence that such measures are of practical value is difficult to assess but clinical impression of the increased well-being which results when these principles are acted upon justifies their adoption in practice.

ANÆMIA

The work of Whipple and his school (Madden and Whipple, 1940; Whipple, 1942) has clearly established that the production of hæmoglobin is dependent upon the quality and quantity of the dietary protein. In recent years increasing evidence has accumulated that tropical macrocytic anæmia is of dietary origin and in particular may be associated with deficiency of dietary protein (Wills and Mehta, 1929-30; Wills, 1933-34; Wills and Evans, 1938; Trowell, 1942, 1943; Upadhyay, 1944; Taylor and Chhuttani, 1945). Experimentally deficiency of the essential amino-acids lysine (Harris, Neuberger and Sanger, 1943), phenylalanine (Maun, Cahill and Davis, 1945) or methionine (Glynn, Himsworth and Neuberger, 1945) has been shown to produce anæmia and, in the case of methionine deficiency, this anæmia has been demonstrated to have the same morphological characteristics as tropical macrocytic anæmia. The work in this field has hardly begun, even in relation to tropical diseases where it would seem to be most relevant, but one significant point has already been demonstrated. It has been shown (Upadhyay, 1944) that an intake of protein, sufficient to prevent anæmia in the non-pregnant woman, is insufficient when she is pregnant. That protein deficiency may play a part in the anæmias following infection or injury has already been suggested. It may also be of importance in the anæmias following exposure to such poisons as trinitrotoluene which are known to combine with amino-acids.

[*October* 23, 1946]

DISCUSSION: OVERACTIVITY OF THE ADRENAL CORTEX

Mr. L. R. Broster: *Adreno-genital syndrome. The results of unilateral adrenalectomy.*—In considering these results I will adhere to Gardiner-Hill's original clinical classification of virilism, which is here supported by a series of 103 unilateral adrenalectomies.

Virilism	Group I	Prepubertal.
	Group II	Postpubertal.
	Group III	Postpubertal of the fat or Cushing's type.
	Group IV	Menopausal.

This condition is distinguished by the appearance of male secondary sex characters in the female, and the more marked this feature is, the greater the suppression of the feminine sex characters and function. It depends upon the age of onset and the degree of hyperplasia of the adrenal glands, consequently there is a wide range of variation in the clinical manifestations. These may be summarized as follows:

In the Female.

(*a*) *Male changes.*—(1) There is a shift towards the male figure involving skeletal structure, muscular development, and disposition of body fat. (2) The clitoris is enlarged. (3) The voice deepens and the larynx is enlarged. (4) Skin changes, involving growth of hair of the male type and distribution, occasionally baldness, coarsening of the texture of the skin with acne.

(*b*) *Female changes.*—(1) The breasts either do not grow, remain small, or may retrogress after full development. (2) The labia and vagina are poorly developed. (3) The uterus may be small and infantile. (4) The ovaries may remain immature, or later become cystic and degenerate. (5) The menses may never appear; if they do they become irregular, scanty or cease altogether. (6) Fertility is decreased.

(*c*) Associated with these somatic changes certain psychological symptoms may appear. These patients tend to react morbidly to their condition, they are depressed, frustrated and feel inferior beings socially. In some there are definite changes in sexuality and personality and in a few frank psychosis.

GROUP I.—15 CASES

Clinical.—Here the symptoms arise before or during puberty, when the secondary sex characters and feminine function fail to appear. Before puberty there may be an enlarged clitoris and a premature appearance of pubic hair. The figure resembles that of a boy more than a girl; and the chest is flat. I have operated on fifteen cases, varying in age from 5 to 31, with an average age of 16: three at the ages of 5, 6 and 7 with signs of precocity, and twelve, after the age of puberty. They all had male figures, hirsuties, deep voices, enlarged clitorides, either small or no breasts and primary amenorrhœa. Their sexuality is indefinite at this early age but in two over the age of 25 male and female tendencies alternated.

Pathology.—The weight of the adrenal glands removed in this series has ranged from 10 to 48 grammes, and there has been little to choose between the size of the two glands. The right adrenal was removed on five occasions, and the left on ten. The larger the gland the more pigmented it is, and resembles the spleen in colour. The cells are strongly fuchsinophil.

The results of estimations of 17-ketosteroid output in mg. per day are as follows:

Patient	Age		Pre-operative	Post-operative
HA	5		6	4
Ba	6		12·4	8·7
Eg	7		37	22
Mot	12		32	25·7
Sim	16		43	16·6
Her	17		54	27
Ron	22		75	58·7
		Average	37	23

It will be seen from these results that the 17-ketosteroid excretion rises with increasing age. The third patient Eg gives a good idea of the inexorable progress of this condition. She had an unusually high 17-ketosteroid output of 37 mg. at the age of 7 when I removed the left and larger of the two adrenal glands. During puberty the clinical condition became worse, and she became an embarrassing social problem to her family. She also had an elder brother with sexual precocity. At the age of 14, her 17-ketosteroid output had advanced to 100 mg. a day, a rise of 63 mg. in seven years, and I removed 19/29 grammes in weight of the remaining adrenal gland, with fatal results. Three patients who had been operated on before these biochemical tests were available showed an average 17-ketosteroid excretion of 60 mg. between two and five years after operation. There have also been two fatalities in this group after unilateral adrenalectomy, and all have passed into a state resembling acute hyperthyroidism, with a falling blood-pressure and a rising pulse-rate. We have found Lugol's solution extremely helpful in these advanced cases after operation but they constitute a major surgical problem.

From our experience so far it would seem that the limits of surgery begin to be reached when each gland weighs over 25 grammes and where the 17-ketosteroid output exceeds 100 mg. a day, but the other patients have done well and lead active and useful lives and, although the post-operative 17-ketosteroid output appears to rise with age, their clinical condition has not ostensibly worsened. The question is whether these results warrant adrenalectomy? The answer to this question is, how much more rapidly would the clinical condition deteriorate with both the adrenals intact. Surely the patient is entitled to whatever amelioration there is, even at considerable risk, for an otherwise desperate and hopeless condition. It is reasonable to argue that earlier operation may offer a better chance in preventing clinical deterioration which seems to become more accentuated during puberty. Consequently I have assessed the results of this group as *in statu quo*.

GROUP II.—88 CASES

This group includes 15 patients with definite psychological symptoms, 14 with the fat or Cushing's type—Group III—and one with the post-menopausal type. The patients, after passing normally through puberty, begin to develop hirsuties and menstrual irregularity, the periods tending to become scanty or to cease for months or even years. The hair is of male distribution and varies in amount and texture. Changes involving the body contour and the secondary sex characters are less prominent than in Group II.

Pathology.—The weight of the adrenal glands removed has varied from 2·3 to 8·8 grammes and the fuchsin reaction is generally present. We have found a definite correlation between the intensity of the stain and the physical condition.

Biochemical.—The biochemical tests have been performed by Dr. Patterson and Dr. Payne, and their results on 41 cases expressed as mg. 17-ketosteroids excreted per day are shown in the table:

	Pre	Post
Group II average 41 tests	17·6	8·5
good results	17·5	6·8
improved	19·1	9·9
i.s.q.	15·1	8·4

The average drop is roughly 50% and where this fall is greater, leaving the post-operative figure low, the results are better.

Clinical results.—The clinical results may be tabulated as follows:

Average age 26. Observed over 16 years. Mortality nil

	Cases	Cushing's	Psychological
Group II	88	14	15
Good	16	2	5
Improved	45	11	8
i.s.q.	10	1	2
Deficient information	14	—	—
Died from other causes	3	—	—

In this group there has been no operative mortality. Should the remaining adrenal hypertrophy or the 17-ketosteroid output increase there is no clinical evidence that they produce any marked deterioration. In suitable cases, therefore, it may be said that unilateral adrenalectomy is capable of arresting the progress of the disease.

Assessment of results.—The clinical results assessed in this table are my own and are based on the psychosomatic reaction of the patient to the operation, and on an evaluation of the alleviation of individual symptoms.

I therefore will proceed to quote observations from two independent sources, which accord in general with my own.

The first is the observations of my old house surgeon, Dr. Geoffrey Andrew, who carried out a postal follow-up, and the second is the record of a typical case by Dr. S. Leonard Simpson.

The report by Dr. Andrew:

(1) *Migrainous headache and depression*.—One or both of these symptoms were present in nearly every case. The headache was abolished in most cases; even where the operation had failed in other respects—e.g. in reducing hypertrichosis or obesity, it succeeded here. Many of the patients were thoroughly grateful for this relief. Some cases were still depressed at times after operation; this was usually because the hypertrichosis had not diminished as much as expected.

(2) *Hypertrichosis*.—Moustaches, beards or side whiskers were usually the main feature that drove the patients to seek advice in the first place. In most cases it produced noticeable psychological

reactions, unless these are to be considered as primary to the syndrome, i.e. part of the syndrome and not a result of it. Most of the patients were prepared to go to much trouble to get rid of the excessive hair.

The operation in some cases only produced good results. The operation only once or twice seemed really to have abolished the hairiness completely enough to allow the patient to call herself normal. In many more cases the adrenalectomy reduced the hirsuties sufficiently to allow of easy removal of the hair with tweezers. A few patients noticed the hair diminished both in abundance and coarseness, and were grateful enough for this. The majority of patients were satisfied with their own degree of improvement. The rest were frankly dissatisfied. This was either because they had observed no improvement, or because they had been led to expect excellent improvement probably by injudicious reports in the public press about it.

I might add that it is as difficult to persuade a woman to shave or remove her hair after operation as it is to dissuade her from operation when this is, as it sometimes is, the main symptom.

(3) *Obesity.*—As obesity was not a feature in all cases, these remarks apply to those where it was present, and the patients were worried by it. In some the operation produced excellent results. In others it was disappointing.

(4) *Periods.*—Many of the patients complained of irregular menstruation. Some had premenstrual dysmenorrhœa and had it severely. Most of the patients obtained some relief in this respect—either relief from dysmenorrhœa, or the occurrence of more regular periods. Some got little or no relief. There was a tendency among the patients to use the improvement in the periods as a yardstick of success of the operation. Those cases where conception occurred were very grateful, and this was one of the really encouraging features of the operation, as sterility was complained of in quite a few cases.

(5) *General health.*—This improved in nearly all cases. Even some of those cases labelled as "neurotic" confessed to me that they had been in better general health than hitherto.

Conclusions.—In well-selected cases the operation is undoubtedly successful in amelioration of the symptoms. In others it has failed. These were cases who pressed for the operation in spite of warning, and the correspondence made this clear.

I consider this is a clear and fair statement of the effects of operation on individual symptoms, and where it succeeds in some it may fail in others. There are obviously complex factors concerned in such a wide range of symptomatology, in which the adrenal plays an important and variable part in a polyglandular syndrome, and it is obvious that the present state of our knowledge does not enable us to predict with precision the amount of benefit that will take place in any given individual.

Dr. S. Leonard Simpson's case:—

A woman aged 26 years had married at the age of 17 and had had two miscarriages. She contracted gonorrhœa from her husband and was operated upon for pelvic peritonitis. She was subsequently divorced, and lost all interest in her sexuality.

For the past fourteen months she began to experience menstrual irregularity with diminishing flow from four to one day with bouts of amenorrhœa. During this time abnormal hair began to grow on her face, legs, and abdomen. She was worried, depressed and self-conscious about her condition and began to shun society.

In June 1944 her left adrenal was removed. It weighed 8 grammes. There were two subcortical adenomas. Vines's ponceau-fuchsin stain gave a moderately intense positive result in the zona fasciculata where the hypertrophy was most marked. The 17-ketosteroid excretion rose from 12·6 in 1943 to 17 and 19·3 mg. in 1944. After operation it dropped to 13·5. Dr. Simpson wrote in August 1946 "you will be very pleased with the result of the operation, and certainly there is positive evidence, both subjective and objective, of a degree of amelioration amounting to clinical cure. Since the operation the hair has completely fallen off the sides of the face and persists on the chin and upper lip in a very much finer texture than before operation. This is also true of her legs, on which, when she shaves them, no black spots are left as there were before operation. She plucks the hair off her face and bleaches the hair, but is certainly successful in her efforts, whereas before operation she could not control the growth of hair. All the hair round the nipples has disappeared; also the upgrowth of hair from the pubis to the umbilicus, which was previously *triangular in form,* but is now limited horizontally, as in the more normal female. My examination confirms the above, and in addition I noticed that the pubic and axillary hair was, if anything, somewhat scanty. The rather unusual feature is her report of loss of hair on the vertex of the head, receding from the temple, immediately after adrenalectomy. It then grew again, and fell out after influenza last winter. It grew again after this, but has now receded from the temples and is coming out in some degree generally. This is somewhat anomalous, as loss of hair of the head is usually associated with growth of hair on the face and body. The texture of the hair of the head is much finer, in contrast to its coarsening and thickening at the same time as the hair grew on her face. She also reported that her breasts had grown to normal size again, and that she had put on a little fat around her hips. She has not, however, gained appreciably in weight. On referring to my previous notes, I see she lost some weight with the onset of the disorder, and I then ascribed it to associated anxiety. However, it may well have been to loss of womanly fat, as occurred in Gordon Holmes' case. A cousin remarked at the onset of the trouble that she became as flat as a board, and lost her womanly shape, which she has now regained. As to menstruation she had almost complete amenorrhœa before the adrenalectomy, but after this there was a slight show (three days later) and ever since she menstruates regularly at intervals of twenty-six days, each menstruation lasting three days and being normal in amount. Her clitoris was enlarged before operation, and has in my opinion receded to normal size. Although restless and somewhat unstable, her general outlook has changed from deep depression and desperation to one of happiness and cheerful expectancy, amounting almost to euphoria. She is friendly with someone whom she anticipates might become her husband.

Psychological results.—Whatever the problem of cause and effect may be there is now sufficient evidence to say that definite improvement in psychological outlook can occur after operation in those patients where it was abnormal before. In fifteen cases there has been improvement in thirteen with failure in two. One of the latter was a German refugee, who had lost her relatives and spoke no English. She was operated upon during the war at a time when I was unable to obtain expert psychological help and guidance. The other lived at a distance and quarrelled with an elderly husband with stepchildren.

As this syndrome carries with it characters which are not normally feminine it is not surprising that these women resent what is fundamentally an unjust biological and social imposition. They become emotionally upset, shy, secretive, self-conscious, frigid and depressed to the point of desperation. Later they may become difficult to manage, wayward, capricious, unco-operative, slovenly in their appearance and habits, and may develop actual delusions of persecution and ostracism. It is not surprising that any amelioration of their physical and functional disabilities should be followed by an improvement in their general outlook. More obscure is their increased sexuality, the feeling of euphoria and sooner or later the loss of their delusional states which follows operation. The biochemical results in this group are too small to form any definite opinion, but the most successful have shown a comparatively low pre- and post-operative 17-ketosteroid output with a post-operative fall of over 50%.

Two of the most advanced cases in this series have been published by Clifford Allen and have remained well for eight and two years respectively.

Dr. E. F. Scowen and Dr. F. L. Warren: *Biochemical aspects of over-activity of the adrenal cortex.*—In 1931 Butenandt isolated androsterone, the first male hormone, from normal male urine. Three years later dehydroisoandrosterone was obtained from the same source. These pioneering researches have been followed in recent years by an intensive search in both normal and pathological urines for other steroid substances and the list of steroids now known to occur in urines from normal or diseased persons is a long and impressive one.

Four different 17-ketosteroids are now recognized as existing in the urine of normal men and women. Two of these are the pair originally isolated by Butenandt, namely, androsterone and dehydroisoandrosterone; the other two are stereoisomers of androsterone. Two of these substances are precipitable with digitonin (dehydroisoandrosterone and isoandrosterone) and are called beta-17-ketosteroids; the other two are not precipitable and are alpha-17-ketosteroids. Normally the alpha-17-ketosteroids account for 90% of the total 17-ketosteroids.

The studies of the Callows and of Hirschmann on urines from ovariectomized women and from eunuchs made it clear that the adrenals are chiefly responsible for the excretion of androgens. All later studies of urines from cases of adrenal hyperplasia or neoplasia have amply confirmed the adrenal cortical origin of the urinary 17-ketosteroids.

Proof of the adrenal origin of 17-ketosteroids led to the suggestion that quantitative estimation might be of value in diagnosis. Such estimation was impracticable so long as capon assay remained the only method for quantitative determinations. A careful study by the Callows of a colour reaction first discovered by Zimmermann led to a practical method for the chemical estimation of urinary 17-ketosteroids.

With the advent of a colorimetric method a wide survey of normal and pathological urines became possible and during the past eight years many thousands of specimens have been examined in laboratories in all parts of the world. We cannot do more than summarize the results under a few rather arbitrary headings.

Excretion of 17-ketosteroids in normal subjects.—It is not possible to classify a urine as male or female on the basis of its ketosteroid content. But the *average* 17-ketosteroid content of male urines is about 5 mg. per day higher than the *average* content of female urines. The earliest work tended to an average value of 8 mg./day for females and 13 mg./day for males. Recent determinations indicate that these values are probably too low and our own results give 13 mg./day for females and 18 mg./day for males. The difference of 5 mg./day may represent the testicular contribution.

Individual variation.—In both sexes the normal physiological range of excretion is very wide. In normal men we have found values from 9 mg. to 28 mg./day. In normal women the range is even wider since values of from 4 mg. to 23 mg./day, have been obtained in apparently normal individuals. It is impossible to stress too highly the importance of bearing in mind the wide physiological ranges of these excretions when interpreting cases suspected of abnormality.

Our experience of a large number of normal and abnormal urines has led us to the conclusion that the excretion in any individual is relatively constant. We have not encountered cases of rapidly fluctuating excretions. In practice this means that one determination of 17-ketosteroid output is usually sufficient to establish the *level* of excretion in an individual.

Our present knowledge of excretion in the normal subject is by no means complete. The available data tend to be crowded in the age-group 20 to 30 years. At both ends of the age-scale our knowledge is much more meagre. In children the excretion increases up to the age of puberty. Talbot quotes values of 1·3 mg./day in children of 4 to 7 years; 4·0 mg. at 7 to 12 years; and 8·2 mg. at 12 to 15 years. We are almost completely ignorant of the excretion in the newborn infant, although such data would frequently be of the highest value. Excretions in old age are still largely unexplored though recent advances in our knowledge of prostatic disease makes such information of great importance.

Levels of excretion in disease.—We may adopt a rough classification of hypofunction and hyperfunction.

Hypofunction: This includes Addison's disease and cases exhibiting pituitary anterior lobe deficiency. In Addison's disease the chief feature is destruction of adrenal cortical tissue and we accordingly find low levels of 17-ketosteroid excretion. Outputs from males tend to be higher than those from females and here again this excess may represent testicular contribution. In the later stages of the disease, however, values approaching zero are found in both sexes.

The effect of anterior pituitary deficiency is presumably caused primarily by absence of adrenocorticotrophic hormone. This is reflected in the extremely low outputs of 17-ketosteroids found in this condition. Administration of adrenocorticotrophin leads to increased output of 17-ketosteroids.

Hyperfunction: Two types may be considered. The first in which the defect is primarily in the adrenal. The second in which the abnormality is one of the anterior pituitary lobe.

In considering non-neoplastic cortical abnormalities we include pseudohermaphroditism in the newborn, and the adreno-genital syndrome, both pre- and post-puberal, in the female.

Interpretation of results on newborn pseudohermaphrodites is impossible at the moment owing to lack of data on normal excretion.

Excretions of 17-ketosteroids in prepuberal virilism caused by benign hyperplasia of the cortex may be extremely high—more than 100 mg./day. Such high values are also associated with cortical carcinoma. But qualitative examination of the steroids from proved cases of benign hyperplasia has shown that, with few exceptions, androsterone is the component that is augmented and that it is this substance that is chiefly responsible for the high total output.

The effect of excision of a hyperplastic adrenal has been, in our experience, by no means regular. In some cases an already high excretion, present before operation, has been increased post-operatively. A possible explanation is that removal of cortical tissue also removes its restraining influence on the secretion of adrenocorticotrophic hormone and this is followed by overcompensated hypertrophy and secretion by the surviving adrenal gland.

Virilism in the adult woman usually results in excretions at or above the upper normal range. Values up to 40 mg./day are regularly encountered. Unlike the prepuberal cases, adult virilism does not lead to the very high outputs of more than 100 mg./day.

Adrenal cortical carcinoma.—Carcinoma of the adrenal cortex in females of all ages is almost always associated with high excretions of 17-ketosteroids. A few exceptional cases have been reported in which the output has not exceeded normal limits. A common factor is the greatly increased excretion of dehydroisoandrosterone and all later work has confirmed the original suggestion of Crooke and Callow that excessive amounts of this steroid are characteristic of carcinoma.

The rarity of adrenal carcinoma in males has limited the opportunities for investigation. In 1936 one of us isolated an unusual 17-ketosteroid from such a case. This substance was considered to be an artefact and the problem arose as to whether its precursor was dehydroisoandrosterone or some other steroid. This problem is still unsolved. There are objections to the assumption that dehydroisoandrosterone is the precursor and it still appears possible that cortical carcinoma in the male does not resemble this tumour in the female in its sterol metabolism.

Hyperfunction of the anterior pituitary.—In this group we may include basophilic and acidophilic hyperplasia or neoplasia.

In Cushing's syndrome excretions of up to 40 mg./day are common. Extremely high outputs are not found.

In the acromegalic, a study of individual cases gave interesting results. Such cases frequently show normal or slightly elevated excretions. But occasionally very high outputs can be detected. In two cases, for example, a male excreted 110 mg./day and a female 70 mg. The excess of androgen in each case was shown to be androsterone. Preliminary results appear to show that the level of excretion is related to the phase of activity of the disease.

As a summary of this brief review of 17-ketosteroid estimations during the past eight years we might repeat what Callow wrote at the beginning of that period, namely: "The independent diagnostic value of urinary 17-ketosteroid excretion is limited to cases of adrenal cortical tumour; in conjunction with other evidence they have confirmatory value in cases in which lowered adrenal cortical function is suspected."

Brief mention may be made of another approach to the study of adrenal cortical function. It has been shown that human urine contains substances resembling in chemical characteristics and biological action certain of the 11-oxycorticosteroids. Urinary extracts have been prepared which are effective in maintaining life in adrenalectomized animals, in protecting such animals against exposure to cold, in preventing water intoxication, and in depositing glycogen in the liver of the adrenalectomized animal. No active compounds have yet been isolated from urine but since the extracts are active with respect to carbohydrate metabolism it is assumed that at least one active compound bears an oxygen atom in the 11-position.

Biological assays show that these substances are excreted in increased amounts by post-operative, burned, or otherwise damaged persons. These findings appear to substantiate the view that the adrenal cortex plays a part in the reaction of the organism to such stresses.

Recently it has been shown that these "cortin-like" substances in human urine may be satisfactorily estimated by chemical methods. By virtue of their side chains all active corticosteroids have reducing properties and they can be estimated by micro-reduction methods. Correlation between chemical and biological assays is good.

Although these researches are still in the exploratory stage some interesting results have already come to light. The normal output of corticosteroids in adults of both sexes is about the same and amounts to about 0·25 mg./day. The physiological variation is wide, since normal excretions of 0·1 to 0·4 mg./day are found. Of conditions so far investigated that lead to increased excretions of "cortin-like" substances, Cushing's syndrome is outstanding. In one patient an output of 12 mg./day was observed, that is, about fifty times the normal excretion. This may be exceptional but two of our own cases showed excretions of 5 and 6 mg./day, and all have been high.

The chemical estimation is non-specific and the possibility existed that the active material might form but a small fraction of the total estimated chemically. However, it appears from some results that we have recently obtained that the chemical method does give substantially a true figure for corticosteroid content of urinary extracts. Corticosteroids can be estimated polarographically by virtue of the characteristic unsaturated ketone grouping situated at the end of the molecule opposite to the grouping involved with reduction. Parallel experiments have shown that at least 50 to 60% of the material determined chemically is active polarographically and hence carries the characteristic corticosteroid group.

Adrenal cortical hyperplasia does not appear to increase the corticosteroid excretion but does increase 17-ketosteroid output. On the other hand, in Cushing's syndrome, the corticosteroid output is very greatly augmented while the 17-ketosteroid excretion is but little elevated. It appears possible, in fact, that the corticosteroid production and the 17-ketosteroid production (or at least production of 17-ketosteroid precursors) are not necessarily linked. Furthermore, it is possible that there are two distinct adrenocorticotrophic hormones elaborated by the anterior pituitary one of which stimulates corticosteroid production and the other androgen production in the adrenal cortex. The androgenic stimulation that can occur in acromegaly and the increased corticosteroid production in basophilism are very interesting in this connexion.

(NOTE.—In quoting actual figures for steroid excretions we have drawn mainly on our own data, that is, on results obtained either at The Chester Beatty Research Institute of the Royal Cancer Hospital (Free), or by Mrs. A. M. Robinson, at St. Bartholomew's Hospital. In discussing the 17-ketosteroid levels of normal urines we have made free use of results recently obtained in joint work with Dr. Morris and Dr. Barnett of the Endocrine Unit of the London Hospital. We should also like to thank all those clinical friends who have placed their material so freely at our disposal.)

Dr. A. C. Crooke: *The altered physiological activity in hyperfunction of the adrenal cortex.*—The endocrine symptoms associated with hyperplasia and tumours of the adrenal cortex are variable. In the adult female the clinical picture of virilism is the most common and it has been dealt with by Mr. Broster. The other well-known clinical picture is that of basophilism but there also exists a number of confusing intermediate types between virilism and basophilism. The final criterion of basophilism is the finding of hyaline basophil cells in the anterior lobe of the pituitary gland which I described in 1935. These cells are found in the pituitary glands of all patients with basophilism whether there is no tumour in any of the endocrine glands, a chromophobe or a basophil adenoma in the pituitary gland, or a tumour of the adrenal cortex, thymus or ovary. Hyaline basophil cells do not occur in the pituitary glands of patients with virilism alone. Thompson and Eisenhardt (1943), writing from the Brain Tumour Registry at Yale, confirmed my findings in a large series of pituitary glands from patients with all forms of basophilism but they could not find hyaline basophil cells in the pituitary glands of any of their patients with virilism, nor in borderline cases in which virilism was associated with glycosuria or hypertension and they did not accept the latter as cases of basophilism on this account. Obviously considerably more pathological material will have to be collected from these intermediate types in order to elucidate this matter.

The reason why some patients with adrenal cortical hyperplasia or tumours develop virilism and others basophilism is not known. Interesting theories about the causation of basophilism have been put forward by Albright (1942) and by Kepler (1945), both of whom regard all forms of basophilism as due to "hyperadrenocorticism," and they consider that the changes in the pituitary gland are secondary to this. My contention that the hyaline change does not constitute a degenerative condition of the pituitary basophil cells has been upheld on cytological grounds by Rasmüssen (1936), McLetchie (1944), and Mellgren (1945). I cannot agree that the pituitary change is necessarily secondary to adrenal cortical hyperfunction but it is probably true that virilism and basophilism are associated with the production of an excess of different types of steroid substances derived from different types of cells in the adrenal cortex. Grollman (1936) has suggested that the androgen secreting cells are derived from a special "androgenic zone" supposed to exist in the innermost layers of the cortex adjacent to the medulla and his theory has been widely accepted. Zwemer, Wooton and Norkus (1938) have shown, however, that the adrenal cortex grows continuously from cells just beneath the capsule which differentiate progressively into the cells of the zona glomerulosa, fasciculata and reticularis and that finally they degenerate in the innermost layer adjacent to the medulla. This is confirmed by our own findings that after hypophysectomy the adrenal cortex atrophies progressively from within outwards and no definite histological abnormality occurs in the outermost zone (Crooke and Gilmour, 1938). If this is true, it is unlikely that a layer of special androgen-secreting cells exists in the region adjacent to the medulla. Cahill, Melicow and Darby (1942) found that adrenal cortical tumours unassociated with abnormal hormone activity were composed of cells which were almost devoid of lipoid vacuoles, while in those which were associated with virilism only there were many vacuoles, and those associated with Cushing's syndrome were choked with vacuoles forming large "foam cells". All these cell types may be found in the normal adrenal cortex and according to Zwemer represent different stages in the elaboration and secretion of its hormones.

It is generally believed that the androgenic steroids are breakdown products chiefly of adrenal cortical but also of certain other steroid hormones. I consider that in hyperplasia and tumours of the cortex associated with virilism they are probably derived from incompletely elaborated hormones. These would be produced by intermediate cells which have not yet developed into ripe secreting cells. The excessive production of the vital adrenal cortical steroids like desoxycorticosterone from fully developed or ripe cortical cells in patients with basophilism would, however, be stimulated by the excessive production of adrenotrophic hormone, evidenced by the hyaline change in the basophil cells of the pituitary glands. This would explain several perplexing observations. It would account for the very high androgen output in patients with virilism caused by adrenal cortical tumours composed of incompletely developed cells and the lower output in patients with basophilism caused by tumours composed of completely developed or ripe cells which produce vital adrenal cortical hormones (Cahill, Mellicow and Darby). Secondly, it would account for the remarkable unilateral atrophy of the adrenal cortex in patients with basophilism associated with a tumour of the other adrenal. Such tumours produce a great excess of vital cortical steroids and it has been shown that certain vital steroids cause cortical atrophy in the experimental animal. Conversely in women with virilism caused by an adrenal cortical tumour the opposite adrenal is not atrophied as would be expected if only incompletely elaborated hormones are being produced. Thirdly, it would explain the occasional incidence of Addison's disease in children with adrenal cortical hyperplasia often associated with pseudohermaphroditism or pubertas præcox without basophilism (Di Ruggiero and Jolly, 1938; Dijkhuizen and Behr, 1940; Butler, Ross and Talbot, 1939; Wilkins, Fleischmann and Howard, 1940; Thelander and Cholffin, 1941). In these patients large amounts of androgens are produced to the exclusion of vital hormones. Finally it would account for the normal or only slightly increased output of androgenic steroids in patients with basophilism without adrenal cortical tumours. In this condition the anterior pituitary gland acting as the instigator stimulates both adrenal cortices and this results in bilateral cortical hyperplasia and the production mainly of completely elaborated vital steroids.

To summarize then, hyperfunction of the adrenal cortex is a difficult and controversial subject. Two main types of hyperfunction are encountered. I have suggested as a working hypothesis that the first, which is associated with the clinical picture of virilism, is caused by an over-production of androgenic substances derived from incompletely developed adrenal cortical cells and associated with no excess of anterior pituitary secretion. The second, which is associated with the clinical picture of basophilism, is caused by an over-production of the fully elaborated or vital adrenal cortical hormones derived from completely developed or ripe adrenal cortical cells and stimulated by an excess of anterior pituitary secretion, which is, in effect, the driving force responsible for this complete development of cells and complete elaboration of hormones in basophilism.

Dr. A. S. Parkes: It is clear from the remarks of previous speakers that estimation of the urinary 17-ketosteroids is now widely used to assist the differential diagnosis of various forms of adrenal over-activity, and that such an estimation may be a useful test. On the other hand, one must be careful to recognize the limitations of the technique. The emphasis on the 17-keto components of the steroid complex arose originally not from any conviction as to their special importance, except in the case of extensive neoplastic growth of the adrenal cortex, but from the fact that they could be estimated fairly easily by non-biological methods. It would be most unfortunate if concentration on the 17-ketosteroids retarded the investigation of other groups of substances and other methods of differential diagnosis.

Dr. S. L. Simpson: I am glad to be able to confirm the excellent result of unilateral adrenalectomy in the case to which Mr. Broster referred; but I may say that I regard the result as exceptionally good, I have seen several patients suffering from the adrenogenital syndrome, who, having undergone unilateral adrenalectomy by Mr. Broster or other skilful surgeons, failed to secure appreciable benefit as regards hirsutism or adipose deposition, although they belonged to the relatively favourable Group II. It is, however, not uncommon for amenorrhœa to be favourably influenced. A long interval between puberty and virilism and a progressive rise in urinary androgens are relatively favourable prognostications.

In one virilized woman of 22, under my care, removal of a large right adrenal adenocarcinoma by Mr. W. M. Dickson in 1938 led to regular menstruation after previous amenorrhœa, but no effect whatsoever on a severe generalized hirsutism. The urinary 17-ketosteroids fell from a pre-operative 143 mg. per twenty-four hours to 25 mg., and after two months rose again to 62 mg. at which approximate level it has remained for six years.

In December 1933 I demonstrated, at the Clinical Section of this Society, a woman with an adrenogenital syndrome in whose urine de Fremery and I had demonstrated, for the first time, a gross excess of comb-growth (capons) and prostate stimulating (castrated rats) hormone. The subsequent development of the work (1936) has opened up wide fields. The 17-ketosteroid assay is a useful blunderbuss method, but concomitant biological assays should not be omitted in research.

they degenerate in the innermost layer adjacent to the medulla. This is confirmed by our own findings that after hypophysectomy the adrenal cortex atrophies progressively from within outwards and no definite histological abnormality occurs in the outermost zone (Crooke and Gilmour, 1938). If this is true, it is unlikely that a layer of special androgen-secreting cells exists in the region adjacent to the medulla. Cahill, Melicow and Darby (1942) found that adrenal cortical tumours unassociated with abnormal hormone activity were composed of cells which were almost devoid of lipoid vacuoles, while in those which were associated with virilism only there were many vacuoles, and those associated with Cushing's syndrome were choked with vacuoles forming large "foam cells". All these cell types may be found in the normal adrenal cortex and according to Zwemer represent different stages in the elaboration and secretion of its hormones.

It is generally believed that the androgenic steroids are breakdown products chiefly of adrenal cortical but also of certain other steroid hormones. I consider that in hyperplasia and tumours of the cortex associated with virilism they are probably derived from incompletely elaborated hormones. These would be produced by intermediate cells which have not yet developed into ripe secreting cells. The excessive production of the vital adrenal cortical steroids like desoxycorticosterone from fully developed or ripe cortical cells in patients with basophilism would, however, be stimulated by the excessive production of adrenotrophic hormone, evidenced by the hyaline change in the basophil cells of the pituitary glands. This would explain several perplexing observations. It would account for the very high androgen output in patients with virilism caused by adrenal cortical tumours composed of incompletely developed cells and the lower output in patients with basophilism caused by tumours composed of completely developed or ripe cells which produce vital adrenal cortical hormones (Cahill, Mellicow and Darby). Secondly, it would account for the remarkable unilateral atrophy of the adrenal cortex in patients with basophilism associated with a tumour of the other adrenal. Such tumours produce a great excess of vital cortical steroids and it has been shown that certain vital steroids cause cortical atrophy in the experimental animal. Conversely in women with virilism caused by an adrenal cortical tumour the opposite adrenal is not atrophied as would be expected if only incompletely elaborated hormones are being produced. Thirdly, it would explain the occasional incidence of Addison's disease in children with adrenal cortical hyperplasia often associated with pseudohermaphroditism or pubertas præcox without basophilism (Di Ruggiero and Jolly, 1938; Dijkhuizen and Behr, 1940; Butler, Ross and Talbot, 1939; Wilkins, Fleischmann and Howard, 1940; Thelander and Cholffin, 1941). In these patients large amounts of androgens are produced to the exclusion of vital hormones. Finally it would account for the normal or only slightly increased output of androgenic steroids in patients with basophilism without adrenal cortical tumours. In this condition the anterior pituitary gland acting as the instigator stimulates both adrenal cortices and this results in bilateral cortical hyperplasia and the production mainly of completely elaborated vital steroids.

To summarize then, hyperfunction of the adrenal cortex is a difficult and controversial subject. Two main types of hyperfunction are encountered. I have suggested as a working hypothesis that the first, which is associated with the clinical picture of virilism, is caused by an over-production of androgenic substances derived from incompletely developed adrenal cortical cells and associated with no excess of anterior pituitary secretion. The second, which is associated with the clinical picture of basophilism, is caused by an over-production of the fully elaborated or vital adrenal cortical hormones derived from completely developed or ripe adrenal cortical cells and stimulated by an excess of anterior pituitary secretion, which

[*October* 11, 1946]

Bone Deformity Associated with Multiple Neurofibromatosis.—NORMAN C. TANNER, F.R.C.S.

The patient, aged 36, complained of a lump on the right leg which had been first noticed at the age of 4. Three years later the lump was diagnosed at a London hospital as congenital syphilitic osteoperiostitis and treated with iodides and leg irons. There is no record of a Wassermann reaction at this time. She was admitted to the same hospital when aged 20, because of a temporary sudden painful increase of the swelling. The Wassermann reaction was then negative.

The patient came to St. James' Hospital in 1941 and was delivered of a male child. It was noticed that she suffered from multiple neurofibromatosis, and her blood Wassermann reaction and Kahn test were negative.

A second child was born in 1944, and after this the leg tumour seemed to become even larger.

Family history.—The patient knows of no other member of her family with neurofibromatosis though both her children have the disease.

Clinical examination.—On examination early in 1946, the patient appeared to be well-nourished and intelligent, with no abnormality of heart, lungs or central nervous system. There were multiple coffee-coloured areas on all parts of the skin, and also numerous sessile and pedunculated nodules typical of von Recklinghausen's disease. The spine was definitely scoliotic, though this was not marked enough to produce any disability.

The left leg appeared normal but the right one had a large rather lobulated mobile subcutaneous tumour on the anterior, medial and to a lesser extent lateral surface of the right leg between patella and ankle-joint (*see* fig. 1).

There was lengthening of the right tibia (right tibia 17¼ in., left tibia 15½ in.) The fibulæ were of equal length, so that the normal relation of internal and external malleolus of the right leg was changed, the two being at the same level.

Many problems still await adequate answers:

(1) Adrenogenital syndrome. With amenorrhœa and hirsutism, the third feature of the syndrome may be either (*a*) developing adiposity or (*b*) loss of fat and muscular development. In either case removal of an adrenal cortex tumour will abolish the abnormality (*a*) or (*b*). Histologically the tumours are identical.

(2) Apparently identical adrenal cortex tumours in:
  (*a*) Women—result in virilism and a high secretion of androgens.
  (*b*) Men—feminization, impotence, and a high secretion of œstrogens.
  (*c*) Boys—pseudo-sexual precocity and a high secretion of androgens.

(3) An adrenal tumour in girls usually produces pseudo-sexual precocity with menstruation at the age of 8 or so, and a general hirsutism of face and body. However, Walter and Kepler recorded a case of menstruation at 19 months, pubic hair, but no body or facial hirsutism, and apparently cured by removal of an adrenal tumour at 5 years of age.

(4) Gross moustache and beard occur in many female members of one family with normal menstruation and normal body-weight. Such women show no other endocrine stigmata and bear children. There, hirsutism is genetically determined.

(5) In the adrenogenital syndrome due to adrenal tumour or hyperplasia, clinical diabetes is exceptional, although the tolerance curve shows a decreased carbohydrate tolerance. Sprague has recently described a woman of 49 with severe clinical diabetes who was cured by removal of an adrenal cortex tumour, but who had no endocrine stigmata.

Dr. J. Patterson: Dr. Warren's figures for 17-ketosteroid excretion of normal adults ranged higher than the usually accepted values, higher than my own findings, and also exceeded the recent values obtained by the more specific polarographic method. His reference to raised output after unilateral adrenalectomy conflicted with my own experience in which post-operative figures had always been the lower. The work of Mason and Kepler seemed to challenge the validity of accepting the excessive excretion of dehydroisoandrosterone as diagnostic of adrenal tumour in female subjects. It was given by only 5 out of 6 of their adrenal tumour cases.

Dr. R. K. Callow: Urinary hormone assays are indirect; the materials detected are metabolites of compounds active in the body. Biological assays do not detect inactive compounds derived from active androgens. Estimations of 17-ketosteroids detect the group present in certain androgens and known to survive metabolic change. While defending chemical methods I should like to emphasize again that the wide range of normal variation of 17-ketosteroid excretion is such that attempts to diagnose minor endocrine disturbances from minor variations are unlikely to be fruitful. Specific chemical diagnosis may be possible by isolation of compounds characteristic of gonadal or adrenal pathological activity, but is difficult and laborious.

shortening, lengthening, cysts of bone, or a tendency to spontaneous fracture have all been described.

Brooks and Lehman (*Surg. Gynec. Obstet.*, 1924, 38, 587), who record the osseous lesion in 7 cases, believe that it results from neurofibromatosis of the periosteal nerves. The growing tumour in the periosteum causes varying degrees of rarefaction and softening of the bone, which later may change to a stage of regenerative osteogenic activity. A thin layer of new bone may even be formed around the tumour producing an X-ray appearance like a bone cyst. Such "bone cysts" on removal are found to have a centre typical of neurofibroma. The lesion appears to share with acute infections the power of stimulating bone growth when situated near the metaphysis, or it may damage the metaphysis and lead to incomplete growth of the bone.

The case shown seems to be one where the tumour originated in the periosteum and some bone lengthening has been caused. It is probable that at an early stage of bone rarefaction and softening, the bone bent, and that this has been followed by regeneration and compensatory hypertrophy.

Ligation of the Inferior Vena Cava for Femoral Thrombosis with Pulmonary Infarction.—J. D. FERGUSSON, M.D., F.R.C.S.

H. J., male, aged 63, was admitted to the Central Middlesex County Hospital on February 4, 1946, suffering from thrombo-phlebitis of the right femoral vein and a recent left pulmonary infarct. Three weeks previously he had had influenza followed by thrombo-phlebitis in the right calf four days later. On the day before his admission to hospital he had experienced pain in the left side of his chest, become dyspnœic and coughed up blood-stained sputum.

On examination.—T. 102° F. Thrombo-phlebitis affecting the right femoral vein and clinical evidence of left pulmonary infarction. Subsequent treatment with sulphathiazole and penicillin brought about some improvement in the inflammatory condition, but on February 27 his sputum was again tinged with blood. After discontinuing penicillin on March 5 he developed thrombo-phlebitis of the opposite femoral vein which in turn was succeeded by evidence of a further pulmonary infarct. In order to minimize the risk of a lethal embolus the inferior vena cava was ligated at the level of the fourth lumbar vertebra. Post-operative heparinization and treatment with dicoumarin were employed, and recovery was uneventful.

No untoward changes occurred as the result of the operation, and the œdema of the legs, already present in association with the thrombo-phlebitis, did not increase. The œdema has now (six months later) subsided considerably, and he is able to walk several miles without undue fatigue. There has been some visible dilatation of the superficial collateral veins in the front of the abdomen, but this, though doubtless partly obscured by his obesity, has been considerably less than anticipated. It appears in general that inferior vena caval ligation is well tolerated, free from objectionable sequelæ, and is worthy of more universal consideration as a prophylactic against pulmonary embolism in cases exhibiting bilateral femoral thrombo-phlebitis.

Von Recklinghausen's Disease.—A. DICKSON WRIGHT, M.S., F.R.C.S.

Little girl, aged 7. Born with a large pigmented mole on the whole of the right half of the chest. Since birth other small lesions, nodules and *café au lait* patches, have developed elsewhere in the body. Recently a diffuse nodular and markedly tender tumour has developed in the left pectoral and axillary region with

X-ray shows the lengthening of the tibia. There is also anterior and medial bowing (fig. 2). There is great thickening of the cortex, maximal at the middle, but evident in the whole length of the bone except its highest and lowest few inches. The medulla is narrowed and there is an area of rarefaction in the upper tibia.

The right fibula has medial bowing and sclerosis of cortex, but the changes are much less than those in the tibia.

Operation.—On May 2, 1946, under general anæsthesia, the tumour was exposed through a long anteromedial incision. The tumour was encapsulated except on the tibial and fibular aspects, where it blended with the periosteum. The tumour was in two main masses, one weighing 1 lb. 10½ oz., the other 6 oz. An area of skin 25 cm. by 10 cm. was also removed to prevent redundancy.

Histological examination.—A neurofibromatous mass in the subcutaneous tissue, showing the unusual feature of a marked hyperplasia of nerve fibres. Also myxomatous change in several areas of the fibromatous part.

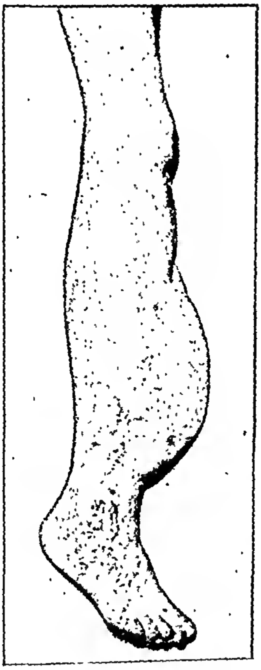

FIG. 1.

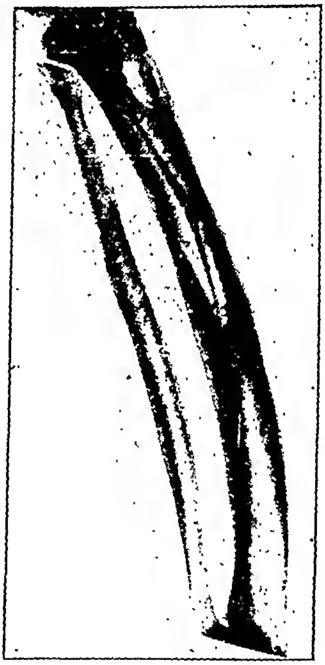

FIG. 2.

FIG. 1.—Side view of tumour before operation.

FIG. 2.—X-ray photograph showing bowing, lengthening, sclerosis and localized rarefaction. (*Photographs* by J. E. Andrews.)

Clinical result.—With the removal of the tumour masses, the underlying bony deformity has become very evident as the tibia can be palpated. The patient has gained complete comfort and is satisfied with the result, so no further cosmetic procedure is contemplated.

Discussion.—The commonest bony lesion described in this disease is scoliosis, and it probably results either from lesions in the intervertebral foramina or from inequality in the length of the legs as in this case. Rarefaction, hypertrophy,

DISCUSSION ON BIRTH CONTROL: SOME MEDICAL AND LEGAL ASPECTS

Dr. Maurice Davidson (The President): Although the title of the Discussion may seem to imply a discussion restricted to certain specific and rather technical matters relation to conception and pregnancy, I hope very much that it will, on the contrary, be dealt with from a much wider standpoint, for indeed it embraces many aspects of human life and conduct, upon which the medical profession, and especially those in general practice, are liable to be consulted, and on which they are not unreasonably expected to be in a position to offer reliable counsel.

Now the ability to do this service to all who require it calls for a wide and sympathetic understanding of human problems as a whole. It needs, moreover, some acquaintance at least with various general principles which must underlie our whole conception of the meaning, the significance, and the objects of birth control, if our advice to our patients is to be of any real value.

It is important that the doctor should realize in what circumstances and for what reasons birth control may be necessary; whether the object of the control is merely to limit the procreation of children, or to preclude it altogether; whether such restriction in any given case is so urgent that if the woman is found to be pregnant, artificial termination of her pregnancy becomes an imperative measure; what are the present accepted indications for the induction of therapeutic abortion. and where is the dividing line between justifiable therapeutic abortion, and criminal abortion, of which, as you know, the law, as it stands at present, takes an extremely serious view. It is important that we should clearly understand just what the law is on this matter. It is also perfectly reasonable for us to debate, if we are so disposed, the question whether any alteration of the existing law is or is not desirable, and, if we feel that it is, then what steps we as medical men should take in a proper and constitutional manner in the endeavour to foster such alteration.

I would appeal to all who take part in this discussion to do their utmost to keep it on the broad basis which I have endeavoured to indicate.

Dr. E. B. Ford (Reader in Genetics in the University of Oxford): *The genetic aspects of birth control.*—It may in certain instances be desirable to advise birth control to patients suffering from hereditary disease and even to their normal relations. In these circumstances, birth control is, of course, directed not to a mere limitation or spacing of births but to ensuring that the individuals in question should beget no offspring. It might be thought that such advice could be given either owing to the possibility of direct and seriously harmful effects upon children or immediate descendants were such to be born, or for a more general eugenic reason: that of spreading dangerous hereditary disease through the population. Yet it will be shown that the latter consideration can rarely of itself be justified as a reason for recommending birth control.

Whether or not patients (or their near relations) suffering from familial disorders can properly be advised to resort to birth control depends upon the way in which such disease is inherited. If it be a simple *heterozygous* defect (often, and usually wrongly, called "dominant" in the literature) none but the affected can transmit the condition, but each sufferer will pass it on to half his or her children. When the disease is serious, this would appear to be reasonable grounds for considering the use of birth control. Moreover, in certain instances, affections so inherited do not manifest themselves until most of the family are born (e.g. Huntington's chorea, which rarely appears before the age of 30). Here even those children who are in reality normal may live under the shadow of becoming ultimately insane, and the fear of transmitting such an affliction to their sons and daughters.

On the other hand, those who suffer from *recessive* familial defects nearly always have normal parents. Their children too will be normal, but all of them will be heterozygotes, transmitting the hereditary condition. Not until two such heterozygotes marry will the disease reappear, and it will do so in one-quarter of the offspring of such a union. In respect of any recessive disease, the population is divided into three classes: those truly normal, those apparently normal yet transmitting the defect (the heterozygotes), and the actual sufferers (the recessives). These three types are disdistributed in the ratio $p^2 : 2pq : q^2$ in the population as a whole. Thus if only one person in 10,000 suffers from a given recessive defect, over 2% of the normal population are transmitting it. Clearly, then, hereditary units, or *genes*, are widely scattered throughout the population even when they are responsible for hereditary defects so rare as to be medical curiosities.

No eugenic measures are of the slightest avail to combat such a situation. Indeed it must be remembered that rare heterozygous, as well as recessive, defects are maintained in the population in equilibrium, balanced by selection tending to eliminate them and mutation tending to increase their frequency. Were it possible to prevent all those suffering from a given recessive disease from a change in the appearance of the overlying mammary gland resembling a precocious development of the organ (fig. 1).

At operation a large racemose tumour with extensive connexions in the axilla was removed; the mammary enlargement was due to an overgrowth of connective tissue such as is often found in the vicinity of the plexiform neuromata of von Recklinghausen's disease.

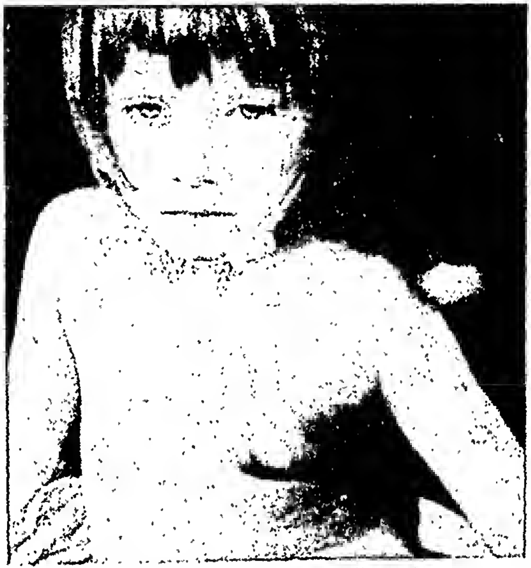

FIG. 1.—Von Recklinghausen's disease with unilateral mammary hypertrophy.

Total Gastrectomy with Œsophagoduodenal Anastomosis.—A. DICKSON WRIGHT M.S., F.R.C.S.

This patient, aged 63, complained of dyspeptic symptoms of a vague kind for one year and radiographic examination showed an extensive filling defect of the greater curvature.

The extent of the growth made a total gastrectomy necessary to get sufficiently wide of the growth. The case is shown to illustrate the method of uniting the duodenum to the œsophagus which is my normal practice. After freeing of the œsophagus from its hiatus in the diaphragm and dividing any fine bands on the outer side of the duodenal curve, there is no difficulty in suturing and no tension after completion, and no special stay sutures to the diaphragm are required. The suturing is done with two layers of fine deknatil interrupted sutures (fig. 1).

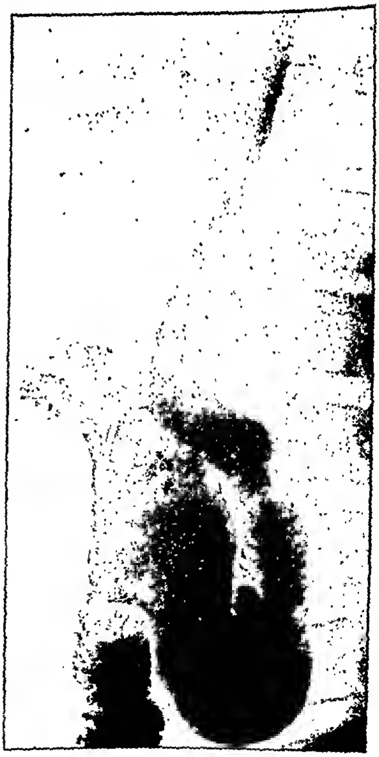

FIG. 1.—Appearance of œsophagoduodenal junction fourteen days after operation showing smooth passage of meal into duodenum and jejunum.

There are many methods of contraception, some of which are admitted to be injurious and others which are apparently harmless on each separate occasion, but which may not be so innocent either directly or indirectly when practised over a long period. The various methods fall under the following heads: (1) Chemical spermaticides; (2) occlusive pessaries; (3) permanent wear of metal contrivances—the so-called wishbone pessary, and the Graefenberg silver ring; (4) Douches, either spermaticidal or irrigation; (5) coitus interruptus.

(1) *Chemical spermaticides.*—A considerable amount of research, described and summarized by C. I. B. Voge in his "The Chemistry and Physics of Contraception", has been done upon the effectiveness of a great number of chemical substances—Voge lists about 147 chemical preparations made in various countries of the world, and a large number of different chemical agents used by manufacturers. The commonest of these substances are boric acid or borates in 44 preparations, chinosol (38), carbon dioxide in foams (34), lactic acid (21), quinine (19), alum (13), acetic acid (11), organic compounds of mercury (5).

The vehicles used are mostly cocoa butter which contains 40% stearic acid and 30% oleic acid.

It is probable that little harm is done by any of the chemical methods now in use. Occasionally there may be minor irritation of the vaginal mucosa, or absorption of quinine, but there is no evidence that these are serious in any appreciable number. We find severe vaginitis equally in all women whether they are young, old, virgins or married women with or without the use of contraception.

(2) *Occlusive pessaries and sheaths.*—The Dutch cap and Stopes cap are rubber obturators. The first occludes the vagina, and the second is a cap fitted over the cervix. The Dutch cap carries a charge of spermaticidal jelly on its upper surface, and may be regarded more as a vehicle for the spermaticide than an actual obturator to the upward passage of spermatozoa. It is probable that the Dutch cap is the most efficient, the easiest to use and least harmful of any method.

(3) The Graefenberg silver ring and the gold wishbone pessary are worn for some weeks or permanently in the uterine cavity. Their effect is to produce very early abortion rather than to prevent conception. As they are foreign bodies in constant contact with the endometrium it is obvious that they are liable to cause pressure ulceration and infection. I have seen two cases of acute salpingitis associated with the wishbone pessary. Moreover, the Graefenberg ring is by no means a certain contraceptive for I have delivered two women of full-term babies with the ring *in utero*. While there is almost universal condemnation of the wishbone pessary there are still a few who advise the use of the Graefenberg intra-uterine ring. If it were reliable there might be something to be said for it, but as it is not only unreliable, but also acts by producing the morbid process of abortion it cannot even be classed as a contraceptive because conception takes place in the tube. It is an abortifacient, and therefore its use is strictly illegal, just as the use of any other instrument for this purpose. On one occasion I found a silver ring embedded in the cervix, and on two other occasions had some difficulty in removing one from the uterine cavity. Retention of a foreign body inside the uterus offends against the basic principles of physiology.

(4) *Douches.*—The function of the post-coital douche is expected to be spermaticidal, but if of any value it is probably as an irrigation. As spermatozoa are found within the cervical canal within fifteen minutes of ejaculation, it is clear that douches are uncertain contraceptives. The materials in common use are water, soap solution, vinegar and hypertonic salt. Of these the most lethal agent is water. The occasional douche after coitus is harmless as well as useless.

(5) *Coitus interruptus* is a common practice, aimed at withdrawal by the male a few moments before ejaculation; for obvious reasons it is unreliable and is baneful to the woman. Apart from being unreliable it is bad because it usually deprives the woman of the orgasm. She is thus left in a state of unresolved pelvic congestion, which I believe is the cause of local troubles such as menstrual difficulties, but chiefly because it leads gradually to a nervous state which manifests itself in the shape of various neuroses. In one of the chief of all the natural functions she is left defeated and deprived. The cumulative effect of many repeated occasions must have a noxious effect on her whole physical and emotional organism.

Late results of contraception.—It is generally agreed that there are reliable methods of contraception which, by reason of the actual method, exert no injurious physical effects whatever.

Let us now consider whether a normal woman suffers from being prevented from conceiving, and passing through pregnancy and labour, or is deprived of any useful physiological influence by interference with the normal act of coitus.

Though there may be little or no harm to the woman due to each act of contraception at the time, it is possible that its long-continued practice may exert harmful effects.

It is alleged (1) that contraception prevents the benefits which undoubtedly occur from child-bearing. Where a normal married woman wilfully remains nulliparous during the whole of her reproductive life we all agree that she has lost some physiological stimulus apart from all the joy that a family of children will bring her. It is, however, only a very small number of normal couples who practise contraception throughout their married lives.

begetting offspring, its frequency, even in the generations immediately following, would be practically unaltered, for the condition is almost entirely transmitted, and concealed, by the (normal) heterozygotes. Similar measures would almost wholly eliminate a heterozygous condition, but it would reappear and rise to its former level in later generations, owing to mutation.

It may be noted, however, that the physician can give one useful piece of advice to members of a family in which a recessive defect is inherited: that it is more dangerous for them than for other people to marry near relatives, as the chance of bringing together two heterozygotes is greatly increased thereby. At the frequency just discussed, when 2% of the population are heterozygotes, the chance that a given heterozygote shall marry a person who is also a heterozygote is 1 : 49 against, if the marriage is not with a relation; but it is multiplied seven times if the marriage be with a first cousin.

Evidently it will be useless to apply general eugenic measures to the elimination from the population as a whole of defects due to single genes, though it may be right and proper to advise birth control to prevent the appearance of such conditions among the immediate descendants of affected persons. This is quite practicable for those which are heterozygous manifestations, but the only recessives for which it is so are those due to genes carried in the differential region of the X-chromosome: those showing total sex-linkage in X.

Such a condition as recessive retinitis pigmentosa (the form unassociated with deafness) is inherited in this way. No man can transmit the disease unless he himself be a sufferer, and he will do so to all his daughters and none of his sons. Affected women are very rare, since they must be homozygous. Heterozygous women, the "carriers" who receive the gene in single dose, transmit it to half their children, the sons develop the disease while the daughters are again "carriers." Thus the sisters of an affected patient can be told that for them there are two alternatives. That is to say, should they marry, either half their sons will be affected and half their daughters will be carriers, or else none of their children will suffer from the disease nor can any transmit it. For such a woman, the probability of these two situations is exactly equal, and she may well feel that she should not beget children. The chance is of course one in four that any woman with an affected uncle (but no affected brother) is a carrier.

Until recently, the same unsatisfactory dilemma faced women closely related to sufferers from hæmophilia, the most famous of the sex-linked recessives. However, Andreassen, working in Denmark, has shown that by appropriate measurements of coagulation time, heterozygous women can be distinguished from true normals. This is a considerable advance. The sisters of hæmophiliacs can now be told definitely that they should not have children or, alternatively, that they can do so with safety.

So far as the use of birth control is concerned, partially sex-linked conditions are in the same position as those transmitted by the autosomes.

This discussion has so far been limited to defects controlled by single genes. These are each rare, though in all they constitute a formidable problem. One very different problem requires at least brief mention here: that of mental deficiency. This of course may be caused in many ways but, apart from the effects of specific disease, it is strongly inherited. In certain instances single genes are responsible, as in phenylketonuria (which is a simple recessive), but in general it has a multifactorial basis. Apart from its high frequency, mental deficiency differs in two ways from the situations so far considered. First, there is a tendency for mental defectives to beget more, not fewer, children than normal, and secondly, multifactorial disorders are much more susceptible to the effects of selection than are unifactorial ones. Consequently, if it were possible to prevent all mental defectives from having children, the frequency of the condition could be materially and quickly reduced. The desirability of birth control measures, and the difficulty of their application, in individual instances of mental deficiency, are sufficiently obvious to need no elaboration.

It will be seen that it is possible to come to certain fairly definite conclusions in regard to those instances in which birth control can reasonably be recommended on genetic grounds. Lists of defects inherited respectively as heterozygous and recessive conditions are available in the textbooks, but special care should be taken in regard to those in which it is stated that the gene is variable in expression or in which the heterozygotes are sometimes affected and sometimes normal. Provided with such data, a practitioner may be able to help a number of patients who require information on birth control on account of inherited disease in their family.

Mr. Aleck Bourne: *The medical aspects of birth control.*—An objective study of birth control from the medical point of view is an inquiry into how far the practice may be harmful or beneficial to the woman. The whole subject is so beset with moral and religious prejudice, and more and more with social and political anxieties that it is not easy to persuade many people to look only at the mental and physical effects it may have upon individual women. Let us examine these in the light of experience and consider first what harm may be suffered.

It is possible that the woman may be injured more or less by the method adopted, either on any given occasion or as a result of long-continued practice, or it may be that the actual prevention of pregnancy or the destruction of the semen will ultimately impair both her physical and mental health.

dyspareunia for which no physical signs can be found, frigidity and refusal. Almost inevitably neuroses of various kinds develop, the woman, driven by her husband, seeks abortion with its risks, she feels self-guilt and often remorse, and a marriage of hope and affection is turned into a squalid bickering partnership.

This is a gloomy depressing story, but all of us who have practised gynæcology over many years know how common and true it is.

Contraception when wisely used can prevent all this. It has arrived as the logical result of the change in our modern times, and will continue because mankind is in the grip of an evolution which is blind and merciless. Those who would abolish contraception must abolish the circumstances which have brought it into being.

Dr. Kenneth McFadyean: I am asked to approach this subject from the point of view of the general practitioner but, as that species includes a great many variants, I shall perhaps be wiser to claim only that I am expressing the views of one general practitioner.

I never cease to be amazed at the ignorance of contraception displayed by many members of our profession. The causes of such ignorance are easy to recognize but I remain amazed at the continued existence of such causes. First the ignorance is due, in part, to the considerable bias of fanatical religion, the authority of which will not allow its adherents to have any contact with, or form any scientific opinion with regard to, the subject. It is profoundly to be regretted that in a matter seriously affecting the health, morality, and happiness of a nation some religious denominations should obstinately maintain an attitude so grossly at variance with the practice of most of their members and all their priests, for celibacy is but one method of birth control. The second and more important cause of such ignorance is to be found in the absence of instruction to medical students in the teaching hospitals. I am not disturbed by the absence of instruction in medical textbooks for, as Trotter was once heard to say, textbooks are invariably wrong.

The intelligent effort to make the knowledge of wise and safe contraceptive methods generally available to all sections of the community is modern, as modern as liberal political philosophy. It is, however, wrong, due either to ignorance or malice, to suggest that this modern social movement is a direct consequence of liberal-minded propagandists. That is indeed putting the cart before the horse. The Rev. Thomas Malthus published his "Essay on the Principles of Population" in 1789 but it was not until 1823 that Francis Place published his "Contraceptive Handbills" and not until the famous trials of Bradlaugh and Truelove in 1877 and 1878 that any really great impetus was given to the movement. The Bradlaugh trial was largely responsible for the formation of the Malthusian League in 1877, nearly one hundred years after the publication of the "Essay". Francis Place, probably influenced by the writings of Benjamin Franklin, foresaw that a more general knowledge of contraception would result not only in a fall in the birth-rate but in many other indisputable benefactions such as earlier marriage, less prostitution, and less sexual abuse and vice of all kinds.

Having narrowed the field of birth control to that of conception control, I would suggest that this is one of the subjects, the total of which is small, upon which the general practitioner can speak with authority, for he probably has a wider experience of the subject than most other people. Let me quite shortly give my views on the methods of such control that have come within my experience during the last thirty years in an extensive middle-class practice. No one will deny that the control of conception is a frequent necessity on grounds of ill-health, both physical and mental. The methods employed to-day in this country are, first, that of "living apart." In most cases this is an intolerable burden to one or both of the partners in the marital union, particularly if they are both young. It is surely doubtful whether this method is ever advised in the case of young people, except by the authority of religious instruction. In one case, where I saw the Church's advice acted upon in this manner, it had the most disastrous physical and moral results for both parties. In this connexion let me say that there is far too little contact between our profession and organized religion in regard to every conceivable sexual difficulty that arises in human life, particularly in the marital state. Indeed the time is long overdue when every person entering the marital union should receive, in addition to religious instruction, advice from members of our profession in regard to the anatomical, biological and psychological differences between the sexes.

Secondly, there is the method of post-coital expulsion and douching, a method which is both unreliable and fraught with many dangers to the woman.

Thirdly, there is the method of female passivity, an unnatural, unhappy and unreliable method baser than prostitution.

Fourthly, we have "withdrawal," a method fraught with the greatest risks from the point of view of successful contraception and one which cannot be advised by any but a person ignorant of the physical and psychological mechanism of coitus.

(2) That contraception may be a cause of sterility in future years. On this there is no firm knowledge, but it is likely that a doctor with a strong prejudice against its use may be led, without evidence, to associate sterility with pre-existing contraception. After having seen even very few consecutive cases of sterility he may form a strong impression that the two are associated, but it is highly unlikely that the ordinary methods of sheath, Dutch cap or chemical pessaries can damage either the function of ovulation or the process of fertilization in future years. An exception of course to this must be the use of the internal pessaries—Graefenberg ring and wishbone—which can cause infection and salpingitis, and also long-continued coitus interruptus which may interfere with ovulation by repeated unresolved congestion of the ovaries.

(3) That certain methods, perhaps all, can and do prevent the absorption of a chemical body from the seminal fluid which has a stimulant action on the full development and maintenance of the female genital tract. Green-Armytage states that, after injection of human semen into immature rats and rabbits, "full development of the female genitalia is due to the absorption by the vagina of hormones from the human semen, and that this hormone is probably testosterone or a hormone allied to it." From this observation he states: "the deduction being that anything or any method which prevents, retards or alters the normal degree of physiological absorption of human semen from the vagina carries with it during the early months and years of marriage the risk of future sterility from failure of uterine development and endocrinal asynchronization."

If Green-Armytage's observations are correct, and his deduction is logical, it is obvious that all forms of contraception cause a serious loss to the woman, but I must add that he is well known to be a very strong opponent of birth control.

Bacsich, Sharman and Wyburn have repeated the work of Green-Armytage and, in addition to human semen, have also injected immature animals with testosterone. They found no changes in the uterus or vagina, nor ovarian stimulation as a result of semen injections into immature rats. Guinea-pigs showed no vaginal reaction and only "slight non-significant uterine hypertrophy" and no ovarian stimulation. Testosterone produced hypertrophy of the clitoris, some vaginal reaction and uterine enlargement.

These observations are supported by the common clinical experience of finding normal development of the whole genital tract, both of structure and function, in virgins of all ages, and the small undersized uterus and smooth vaginal mucosa in married women, anxious to have children, who have never used contraceptives. The evidence therefore that prevention of the contact of unaltered semen with the vaginal mucosa leads to failure of genital development is so far flimsy.

The very large majority use contraception to delay or space their pregnancies. We must conclude therefore that harm to the woman or couple does not follow the methods used except coitus interruptus and permanent intra-uterine pessaries. Nor is it likely that the woman suffers any physiological loss from interference in absorption of some hypothetical substance in the semen. She will, however, suffer a loss of fulfilment if she voluntarily deprives herself of all child-bearing, and a lesser loss if the family is limited to one or perhaps two. Here the family unit, if it consists of only one child, also loses something which moderate, or even large families enjoy, provided economic circumstances are adequate.

Benefits of Contraception

Having discussed the possible harmful effects of contraception what is there to be said for the credit side?

The power to prevent child-bearing is a boon to some women where it is used only to avoid too frequent pregnancies, in other words, to space their children. Individual circumstances of personality, character and economics of course differ, and no rules can be laid down, but, in general, it is right to say, that where contraception is not used to prevent all children, but only used, not so much to limit the number, but to space them, it is wholly good.

I have spoken of how far the methods and effects of contraception may damage the woman, but equally we should ask, with the same anxiety, how far unlimited and annual child-bearing will also injure the woman physically, or indirectly disrupt her marital relations. We all know that some women are able to have many children at frequent intervals without any harm whatever. We are reminded of the Victorian days when large families were common and our grandmothers lived through the happy content of their years. But the epoch has changed, and, though we may deplore it, the change is inexorable and irreversible. The impact of a new way of life and a new set of economics has fundamentally altered the attitude of mind of womanhood to child-bearing.

The state of the woman of to-day who has rapidly repeated pregnancies must therefore be considered, not in terms of the Victorian age, but in the light of the circumstances of our own times. The result of the influence of modern conditions is that the majority of women, both of the middle and working classes, who become pregnant year after year, not only lose the happiness of their married lives, but become spiritually and emotionally celibate.

The physical act of coitus becomes an occasion of fear and apprehension. Thus is lost the libido on which much of married happiness during the early years is founded. This often leads to

Finally we must recognize that all our efforts have failed to prevent the number of illegitimate births from rocketing, at least in the recent war, and immediate post-war, periods. Before the war the annual figure of such births in this country was fairly steady at 25,000 but in 1942 it had risen to 40,000 while last year it rose to over 50,000. I am not at the moment prepared to advocate the propagation of conception control among unmarried women but opposition to such a procedure comes ill from those who are insistent upon the male sex being given every conceivable protection against the possible consequences, of another kind, resulting from illicit sexual communication.

Sir Travers Humphreys: The practice of contraception is not unlawful. Marriage is a contract, of which consummation is an implied condition: and non-consummation due to impotence has been for centuries a ground for annulment. Last July the Court of Appeal held that a marriage is not consummated unless penetration is followed by emissio seminis; thus, a wife may seek annulment if the husband wilfully refuses intercourse except with the use of a rubber sheath. It will be interesting to learn the views of their Lordships when the converse case arises—if the wife after full connexion and without the knowledge of the husband excludes the chance of pregnancy by the use of a syringe, will the husband be entitled to a decree?

Abortion is undoubtedly criminal; therapeutic necessity is the only ground on which abortion can be approved or excused, and I sincerely hope that neither by Parliament nor by the judges will the decision of Mr. Justice Macnaghten in 1937 be altered. The matter is not so much one of law as of the good sense of the jury. The test is, does the doctor honestly believe that it is absolutely essential in the interests of the woman's physical or mental health to perform the operation? Here the doctor is put in the same place as an operating surgeon in hospital. To cut off a leg is a serious assault, and the only reason such an act is not criminal is the interest of the patient's health and life. The patient's personal wish affords no defence in law.

As to sterilization of the male, I do not know enough of the manner of performing the operation to enable me to express an opinion as to its legality. If it involves the maiming of the man it may well be unlawful and the consent of the patient will not excuse the practitioner since no man can lawfully authorize his own maiming unless the operation in in the interest of his health.

Mr. Reynold Boyd deprecated the inclusion of discussion on abortion at a meeting on birth control which, to the majority of people, meant contraception. He asked about the legalities of voluntary male sterilization by vaso-ligation for convenience and not specifically for health reasons—for instance of a man with 4 children and a wife of 43 where fear of further pregnancy was ruining the marriage. He thought the original law referred to castration and not ligation which in any case was reparable. Finally he thought that the recent definition of emissio seminis should be revised for divorce purposes.

Mr. V. B. Green-Armytage began by referring to the death of Dr. Pangloss in Voltaire's Candide where he, though in dire straits, curses Candide and says all is well, all is for the best. Is all well to-day, when at many Centres throughout the country young unmarried girls can be fitted with birth-control gadgets so that they can "walk out" with their boy friends? The spread and underground percolation of such birth-control information has resulted in an immeasurable degree of promiscuity, illegitimacy, venereal disease, abortion and subsequent sterility.

The speaker then continued: As a result of the use of birth control for any length of time before conception of the first baby, there is an ascending spiral of primary sterility in this country, which so often leads to the divorce courts.

It is one of the first axioms of eugenics that without numbers there can be no variation. Therefore it is not to be wondered at that no genius has been born to this or any other country during the last 40 years.

The pernicious Baldwinian "Safety First" doctrine of young married people to-day, has resulted in vast numbers of frustrated husbands, inhibited wives, perverts, introverts, nancies and pansies. Hence psychiatrists have come into their own.

Another result of the one—two family is that we are fast becoming a nation of old people whose old age pensions will have to be paid for by a groaning and complaining body of youth.

It is my belief from what some of the medical speakers have said that they have in mind to stimulate the start of a new diploma for our graduates as well as post-graduates to be called the D.D.C.F.—that is the Diploma for Dutch Cap Fitting. These people who advocate unremitting birth control are a danger to the State and our Empire. Indeed all is not well. Therefore let us with Candide "cultivate our garden." Mr. Bourne referred to some experiments of mine which he states have been disproved by another worker. May I say that this research has since been repeated using homologous semen with positive results in 80 per cent. of cases, and will be published shortly. They show that there is a principle or agent in the semen which promotes growth, indubitably.

Mr. Anthony W. Purdie asked for further information on the legal issues involved in the sterilization of the husband for conception control. In reply to a previous speaker Mr. Justice Humphreys had

Fifthly, there is the male contraceptive sheath. This is a comparatively old method, dating from the linen sheath in use in the sixteenth century, but it is open to the charge of unreliability and to the serious objections that it separates the partners to the act and deprives the women of the influence of seminal fluid. I refer to the seriousness from the physical and æsthetic point of view, not from the legal point of view.

In the sixth place is the use of chemical contraceptives and the wearing of an occlusive pessary by the female. Some authorities apparently regard the occlusive pessary as having originated with the Mensinga Cap in the '80s but Marie Stopes found a German description as early as 1838. She regards it as but a modern version of the five thousand years'-old Egyptian "Barrier". In more modern times we find the use of half a lemon advised by Casinova, in the latter part of the eighteenth century.

The use of chemical contraceptives alone is certainly not reliable. The use of an occlusive pessary alone is probably more reliable but a combination of the two is in my experience infallible, provided the woman is properly examined and provided with appropriate instruments and advice by the medical practitioner. For over thirty years I have advised none other than this method for regulating conception. It should be remembered that this method is not advised so much as a method of permanent or even indefinite contraception but as a method for regulating conception. So far as my experience goes it is utterly devoid of any reasonable objection. It is infallible; it is non-injurious to either party; it does not interfere with the anatomical or aesthetic relationship of the partners. All it attains is the prevention of conception. Many authorities, including Van der Velde, believe that the presence of seminal fluid in the vagina has some not inconsiderable influence on the woman. If this belief is well founded, modern contraception does not mitigate against such influence.

One must pass some comments on the supposed objections to this method. I am not concerned with the irrational authoritarian objection of certain religious denominations, for such bodies do not in fact object to birth control, or even conception control of the more undesirable kind; they only object to the easy and pleasant method of conception control and would add further trial and tribulation to those already afflicted, with no justification, and no solace to offer, other than that "these things are sent to try us". The same might be said of earthquakes or senility, with a great deal more reason, for as yet we have little to offer to combat such evils.

I have never seen such a method, used with discrimination, result in harm to either party. I have never seen it result in sterility, even when it has been practised for some years after marriage; that it may result in non-consummation is another matter. I have never seen a "Malthusian Uterus" and am not prepared to discuss such nonsense as the production of uterine fibroids, carcinoma uteri, urethral caruncle or even chronic appendicitis by this method of contraception. Not only have I never seen any of these consequences but never has any disease in the female pelvic organs, in my practice, been attributed by a consulting gynæcologist to this or any other method of contraception. Perhaps my consultations have been too few.

Admittedly in years gone by one did see cases of vaginal irritation due to cocoa butter or quinine. Such cases never had serious results nor ever resulted in chronic inflammation. These minor troubles are rapidly disappearing with the advent of latex rubber occlusive pessaries and more modern non-irritant chemical contraceptives. When one reads some of the biased views expressed, even by members of our own profession, in regard to the injurious results of such practices, one wonders whether those holding such views are blind to Nature's failure to sterilize the human penis and to the aggravation of its condition by the dirty clothing and dirty occupations imposed upon men by civilization.

I am strongly of the opinion that within the period of my medical experience inflammatory and ulcerative conditions of the vagina and cervix uteri have shown a great reduction in numbers. If I am right in this opinion, it is possible that one of the factors producing such a result may be the more widespread knowledge of advisable methods of contraception.

Next comes the question of abortion. The intense suffering and shocking loss of life through illegitimate abortion have always horrified me, particularly as I have always believed that these tragedies, in the majority of cases, were to be found in married women, already mothers of one or more children. Many years ago I shocked some of my colleagues by publicly advocating the legalization of abortion. It seems likely that the dissemination of knowledge of contraception has reduced this wastage of life. Carlyle's crabbed satirist said "A judicious man looks at statistics not to get knowledge but to save himself from having ignorance foisted upon him". Statistics prove nothing. They are too often but a feeble expression of a doubtful opinion. However, here are statistics which *may* support an opinion firmly held. In the Registrar-General's reports deaths due either to abortion, or to causes associated with abortion, in 1930 were 588, by 1935 the figure had fallen to 464 and by 1940, the last year for which I can find the combined figure, the number had fallen to 268. It should be noticed that these figures cannot be affected by the discovery of penicillin. If I am right in thinking that the regulation of conception is one factor in this welcome improvement, then I would gladly see some degree of compulsion introduced in the dissemination of contraceptive knowledge.

Section of the History of Medicine

President—Sir ARTHUR MACNALTY, K.C.B., M.D.

[*October* 2, 1946]

The Evolution of Preventive Medicine in England

PRESIDENT'S ADDRESS

By Sir ARTHUR SALUSBURY MACNALTY, K.C.B., M.A., M.D., F.R.C.P.

IN the twilight of civilization, when primitive man lived in caves and encampments, and when isolated groups of families merged into tribes for purposes of security, defence and offence it is possible to trace the beginnings of preventive medicine. The biologist tells us that in the earliest stages of human existence man must have perceived some glimmerings of the need for health preservation, which pointed out steps of quest or avoidance in the interests of self-protection. The perils of hunger and thirst, the poisonous nature of certain foods and waters, the fatality of malarious regions, the dangers of extreme heat and extreme cold, the destruction wrought by floods and drought, outbursts of infectious disease and pestilence in the tribe: these are examples of conditions inimical to health, which must have been familiar to our primordial ancestors, and must have early inclined them to desire to escape disease and to devise measures for doing so.

Then, again, communal effort in agriculture promoted good nutrition, and provision was made against scarcity and famine by the erection of public storehouses for food distribution in the common interest. Water supply was always of imperative necessity, and this led to the invention of mechanical devices for its conduction and storage. At first the necessity on grounds of health for an unpolluted water supply was not realized, but the religious veneration for rivers, streams and founts must have promoted this to some extent. River-gods and naiads were the guardian deities of running water, and deliberate wilful pollution of the river that gave drinking water was impiety and sacrilege. The care directed to water supplies led on to systems of drainage, primarily, for the protection of agricultural land and afterwards for the removal of dejecta. The discovery that accumulations of household refuse and filth were of value as manure led to the removal of the insanitary "kitchen midden" about the homes of our ancestors, and scavenging came into use with consequent benefit to health.

EGYPTIAN AND GREEK MEDICINE

As for the prevention and treatment of disease in primitive times, sickness, especially epidemic disease, was regarded as a punishment from the gods or tribal deities to be expiated through the agency of witch-doctor or priest. It cannot have been long, however, before observation taught men that contagion played a part in the dissemination of epidemics.

"Latona's son a dire contagion spread,
And heap'd the camp with mountains of the dead."
Iliad, Book I.

been emphatic that the operation was illegal, and that a doctor who performed such an operation would do so at his peril. The hypothetical case, however, which prompted this statement of opinion was one in which the operation had been proposed merely on the grounds of the couple's already having a sufficiency (for them) of children. But a request for the sterilization of the male was sometimes made in quite different circumstances. Take, for example, the case of a woman suffering from organic heart disease who had already two or three children. As doctors we considered that she should have no further children because of the organic disease of the heart. The normal recommendation would be that she should be sterilized. In these circumstances, however, a husband from time to time asks that he—rather than his wife—should be sterilized on the grounds that his wife has already suffered enough. In such a case what would be the legal position if his request were granted? Would a doctor sterilizing a husband under similar circumstances be likely to run into legal trouble?

Dr. Letitia Fairfield said that there were many circumstances which made it unwise to sterilize healthy persons on request. If for example, a woman had such serious heart disease or tuberculosis that she was permanently unfit for child-bearing and was unfit even to undergo a sterilizing operation herself, she was obviously liable to die before very long. Suppose the husband who had been sterilized then wanted to remarry—what then? Would it be to his ultimate good or that of his future wife that the surgeon had acceded to his request? Nor were motives behind the "requests" always altruistic. She could recall the case of a man who was living with a mentally defective girl and greeted the social worker who called to make enquiries with the remark "You needn't worry about her having a baby, I had an operation done in S. America so that I can enjoy myself when I like and not bother about the results." In the U.S.A. she met two—or more—surgeons who had informed her that they had seen such tragic results from sterilizing healthy people that they had decided to abandon the practice.

As for the recent legal decisions in birth control and consummation of marriage, as described by Mr. Justice Humphreys, it seemed to her that it left the law in a chaotic condition. The decision of the Court of Appeal that valid consummation depends on a quite unprovable event—(*an ejectio seminis*) is highly unsatisfactory. So was the decision of Mr. Justice Jones in the Divorce Court, for it was apparently now possible for a wife to obtain an annulment if her husband had been sterilized without her knowledge, or used (for example) two of the commonest methods of male contraception, but gave no remedy to the husband whose wife had been operated on or who used the common methods of female contraception. It was possible that both these decisions were made under misapprehensions of physiological facts, but in any case the legal position should be clarified without delay.

Dr. Alexander Kennedy: Apart from a few uncommon conditions, mentioned by Dr. Ford, in which the mode of inheritance was understood, the only group of any numerical consequence in which birth control could be advised as a eugenic measure was the mentally defective group in which the inheritance was multifactorial. There was evidence that among high-grade defectives who are free in the community and able to procreate, the intelligence level of the offspring tends to be at the average of the parental levels. Although limitation of the families of this group was most desirable, it was the daily experience of psychiatrists that attempts to use birth control appliances by such patients were very often unsuccessful The same was true of many neurosis-prone and psychopathic patients in whose condition inherited factors were almost equally probable and who were impulsive and incompetent in managing their affairs. Birth control technique in this group was likely to be unsuccessful for exactly the same reasons. There was thus a tendency for birth control to limit the families of those who were able to pass the test of competence with the apparatus, while merely creating a sense of false security in the less capable and stable members of the community. Few would doubt the value of birth control methods in protecting vulnerable personalities from the extra strain of inopportune childbirth, but its value as a eugenic measure was probably very limited until the methods employed were more foolproof.

Dr. Edward F. Griffith could not agree with what Mr. Green-Armytage had said. He challenged him to name a single Women's Welfare Centre in the country that taught young girls contraceptive methods so that they could go down the street and have affairs with their boys. Such an assertion was a gross misrepresentation of the whole purpose, not only of Women's Welfare Centres, but of contraception in general. It was true of course, that contraception could be abused, but so could any other scientific discovery. Contraception and abortion were entirely different and should never be considered in the same category. Abortion was a destruction of life, whereas contraception merely prevented fertilization—the one was destructive and the other was essentially constructive provided that it was used for the purposes that the other speakers had already indicated, i.e. proper spacing of children and the achievement of mutual harmony in marriage. From his own experience both as a general practitioner for fifteen years and as a specialist in marriage problems for ten, he agreed entirely with what Dr. McFadyean had said. Contraception, one of the most valuable discoveries of the age, *had* come to stay. Our duty was not to condemn it but to see that it was properly used.

THE EIGHTEENTH CENTURY

It was in the succeeding century, the eighteenth century, that a galaxy of medical practitioners appeared in the firmament of Medicine, whose clinical investigations form the basis of modern preventive medicine.

Before touching on their discoveries mention should be made of a non-medical research worker, whose studies contributed largely to advances in physiology and preventive medicine. This was the Rev. Stephen Hales (1677-1761). His *Vegetable Staticks* (1727) marks the early stages of our knowledge of the physiology of plants; his *Haemastaticks* (1733) treated of blood-pressure and circulation of the blood. Besides a work on dissolving stone in the bladder, he wrote in the *Philosophical Transactions* on ventilation, electricity, analysis of air, &c. He also invented ventilating machines and machines for distilling sea-water and for the preservation of meat.

It was, as I have just said, in the practice of clinical medicine that the science of preventive medicine now began to emerge, and it is a remarkable feature of this eighteenth-century work that it was done by men working independently at their individual problems, and, for the most part, ignorant of the others' investigations. In epidemiology they were the disciples of Thomas Sydenham, observers of the clinical features of epidemic disease, the influences of external environment, the paths of contagion and infection, and the effects of climate and season.

> "Huxham of Totnes studied typhoid, typhus, scurvy and diphtheria; Richard Mead, plague and scurvy; the illustrious Heberden, diphtheria, angina, chicken-pox, night-blindness, smallpox and 'epidemical colds'; Fothergill, epidemic sore throat; Haygarth of Chester, smallpox, typhus and rheumatic fever; Willis, epidemic diphtheria, typhoid and puerperal fever; and Withering of Shropshire, scarlet fever, heart disease and tuberculosis" [4].

In connexion with the plague and sweating sickness of the sixteenth century, methods of medical notification including Bills of Mortality[1], of isolation of infectious persons and contacts from the community, of fumigation and disinfection had been introduced. These methods were now applied with success to other forms of infectious disease.

The eighteenth century also saw the beginnings of university education in preventive medicine [5]. In 1786 Johann Peter Frank was appointed director of public health of Austrian Lombardy, and his international fame led to the creation of the first Chair of Public Health in Edinburgh University. Dr. Andrew Duncan, who became Professor of the Institute of Medicine in Edinburgh in 1789, began in 1795 a series of lectures on forensic medicine, including "medical police", in which he dealt with both personal and environmental health. In 1798 Duncan presented a memorial, as the outcome of which in 1807 George III granted a commission creating a professorship of medical jurisprudence and medical police "as taught in every university of reputation on the Continent".

ADVANCES IN OBSTETRICS AND CHILD WELFARE

In obstetrics too further advances were made, for the high rate of mortality in childbirth began to excite medical if not public concern. William Harvey in 1651 had produced *De Generatione Animalium*, which discussed the anatomy and physiology of the human embryo and placed the study of midwifery on a scientific basis. Peter Chamberlen's discovery of the obstetric forceps by the eighteenth century was no longer a secret, and Dr. John Mowbray and Mr. Edward Chapman were using it in general practice. Sir Richard Manningham in 1739 established a lying-in hospital in the Infirmary of the Workhouse of St. James, Westminster, where instruction was given to medical students and midwives [14].

---

[1] The London Bills of Mortality were records of burials and baptisms kept by the Company of Parish Clerks.

Such a concept must have been known to the Egyptians, for Egyptian medicine is regarded by Hebrew and Greek historians as the original source of medical knowledge. According to Herodotus, Egyptian medicine was specialized to a degree comparable only to that seen in the United States to-day. He wrote:—

> "The art of medicine is thus divided amongst them: each physician applies himself to one disease only and not more. All places abound in physicians; some physicians are for the eyes, others for the head, others for the teeth, others for the parts about the belly and others for internal disorders" [1].

"Moses was learned in all the wisdom of the Egyptians", and has been rightly termed the first Minister of Health, for the Book of Leviticus is a compendium of sanitary law. He enforced compulsory notification, and set out in detail systems of isolation and of disinfection of patients and their dwellings. Assyria had a Code of Medicine (the Hammurabi Code), while Greek medicine in many of its practices was more advanced than British medicine in the nineteenth century. "Like everything that is good and durable in the world, modern medicine is the product of the Greek intellect", said Osler. The practice of hygiene, life in the open air, sunlight-therapy and a balanced dietary were familiar to the Greeks in the fifth century B.C. They had the sun-temples of Cos and Epidaurus, the health principles of Hippocrates, Alcmaeon and Empedocles, and Greek medicine was active and progressive, until it became doctrinal in Galen's interpretation of the Hippocratic writings. Even when the Arabians disseminated Greek medicine to Western Europe, the teaching intended to stimulate progress paradoxically retarded it through its very authority. There was one great exception: Offspring of Greek Medicine, by the eleventh century Salerno was the most celebrated medical school in Europe. It taught hygiene and preventive medicine, and issued the first regulations requiring qualification and licence for medical practice.

PUBLIC HEALTH IN MEDIÆVAL ENGLAND

Pestilence has always been a stimulus to public health. In England leprosy brought about the establishment of leper hospitals by the ecclesiastical authorities, the beginnings of our hospital system, and methods of notification and isolation. Plague demonstrated the necessity of sanitation in the hovels of the poor. The first Sanitary Act was passed by the English Parliament at Cambridge in 1388; it was followed by quarantine laws, by the appointment of scavengers, by sanitary watchmen, and by penalties for the concealment of infected persons.

The Renaissance and the knowledge of Greek authors produced great medical schools at Padua and Montpellier, and the Oxford humanists brought the new learning to England. Linacre organized English medicine, and helped to found the College of Physicians in 1518, of which he was the first president. Thomas Vicary's work in uniting the Corporation of Surgeons with the Barber-Surgeons and in promoting the teaching of anatomy and surgery led immediately to progress in British surgery. Sir Thomas More, as I have shown elsewhere [2*a* and *b*], was a great health reformer. We have to wait until the nineteenth century for a man of equal vision and breadth of view to appear in Edwin Chadwick. Other pioneers in public health of the Tudor Age were Sir Thomas Elyot, diplomatist and author, William Bullein and Andrew Boorde. From Padua Vesalius, Fabricius and William Harvey brought new learning and perception into the healing art. The golden key of the Renaissance unlocked doors which led to a wonderful domain of natural science and experimental medicine, whose confines to-day are still unlimited and unexplored.

THOMAS SYDENHAM AND OTHERS

The seventeenth century saw the foundation of the Royal Society in 1662. Thomas Willis advanced medical knowledge, Daniel Whistler and Arnold Boot identified, and Francis Glisson, the morbid anatomist, gave the first scientific account of rickets, Christopher Bennet and Richard Morton described pulmonary tuberculosis; and the study of medicine and surgery, based on experiment and observation, went forward linked with discoveries in biology, comparative anatomy, chemistry and physics, which threw fresh light on the problems of health and disease.

Thomas Sydenham (1624-1689) reinterpreted the Hippocratic conception of epidemics and led the way to the domain of modern epidemiology. He renounced unsupported authority, dogmas and theories and went to Nature. "He laid down the fundamental proposition, and acted upon it, that 'all diseases should be described as objects of natural history' " [3].

THE EIGHTEENTH CENTURY

It was in the succeeding century, the eighteenth century, that a galaxy of medical practitioners appeared in the firmament of Medicine, whose clinical investigations form the basis of modern preventive medicine.

Before touching on their discoveries mention should be made of a non-medical research worker, whose studies contributed largely to advances in physiology and preventive medicine. This was the Rev. Stephen Hales (1677-1761). His *Vegetable Staticks* (1727) marks the early stages of our knowledge of the physiology of plants; his *Haemastaticks* (1733) treated of blood-pressure and circulation of the blood. Besides a work on dissolving stone in the bladder, he wrote in the *Philosophical Transactions* on ventilation, electricity, analysis of air, &c. He also invented ventilating machines and machines for distilling sea-water and for the preservation of meat.

It was, as I have just said, in the practice of clinical medicine that the science of preventive medicine now began to emerge, and it is a remarkable feature of this eighteenth-century work that it was done by men working independently at their individual problems, and, for the most part, ignorant of the others' investigations. In epidemiology they were the disciples of Thomas Sydenham, observers of the clinical features of epidemic disease, the influences of external environment, the paths of contagion and infection, and the effects of climate and season.

> "Huxham of Totnes studied typhoid, typhus, scurvy and diphtheria; Richard Mead, plague and scurvy; the illustrious Heberden, diphtheria, angina, chicken-pox, night-blindness, smallpox and 'epidemical colds'; Fothergill, epidemic sore throat; Haygarth of Chester, smallpox, typhus and rheumatic fever; Willis, epidemic diphtheria, typhoid and puerperal fever; and Withering of Shropshire, scarlet fever, heart disease and tuberculosis" [4].

In connexion with the plague and sweating sickness of the sixteenth century, methods of medical notification including Bills of Mortality[1], of isolation of infectious persons and contacts from the community, of fumigation and disinfection had been introduced. These methods were now applied with success to other forms of infectious disease.

The eighteenth century also saw the beginnings of university education in preventive medicine [5]. In 1786 Johann Peter Frank was appointed director of public health of Austrian Lombardy, and his international fame led to the creation of the first Chair of Public Health in Edinburgh University. Dr. Andrew Duncan, who became Professor of the Institute of Medicine in Edinburgh in 1789, began in 1795 a series of lectures on forensic medicine, including "medical police", in which he dealt with both personal and environmental health. In 1798 Duncan presented a memorial, as the outcome of which in 1807 George III granted a commission creating a professorship of medical jurisprudence and medical police "as taught in every university of reputation on the Continent".

ADVANCES IN OBSTETRICS AND CHILD WELFARE

In obstetrics too further advances were made, for the high rate of mortality in childbirth began to excite medical if not public concern. William Harvey in 1651 had produced *De Generatione Animalium*, which discussed the anatomy and physiology of the human embryo and placed the study of midwifery on a scientific basis. Peter Chamberlen's discovery of the obstetric forceps by the eighteenth century was no longer a secret, and Dr. John Mowbray and Mr. Edward Chapman were using it in general practice. Sir Richard Manningham in 1739 established a lying-in hospital in the Infirmary of the Workhouse of St. James, Westminster, where instruction was given to medical students and midwives [14].

---

[1] The London Bills of Mortality were records of burials and baptisms kept by the Company of Parish Clerks.

William Smellie, a Scot, who had learned his midwifery in Paris, settled in London, and as practitioner, teacher and writer advanced knowledge of his subject. He elevated the status of the man-midwife; introduced forms of technique for the measurement of the pelvis, safe use of the forceps, diagnosis and treatment of *placenta prævia*, and improved modes of version. Another Scot, William Hunter, was primarily an anatomist, but he was also a practising obstetrician. His methods were conservative, but they were eminently sound. Hunter's pupil, Charles White of Manchester, in his excellent treatise, *On the Management of Pregnant and Lying-in Women and the means of curing but more especially of preventing the principal disorders to which they are liable*, published in 1773, dealt with the general management and hygiene of childbirth, ante-natal supervision, and the cause and prevention of puerperal fever. By his hygienic methods—scrupulous cleanliness, fresh air, suitable temperature of the lying-in ward, dietary and disinfection—he claimed that he had never lost a patient from puerperal fever. These three men, Smellie, Hunter and White, so greatly advanced obstetrics that further improvement was impracticable until Simpson discovered chloroform anæsthesia and Lister antiseptic surgery.

Side by side with improvement in maternal mortality can be noted the beginnings of infant welfare in isolated attempts to control the high mortality of infants and children, which amounted in 1730-49 to as much as 74% of children born. Lettsom and Cadogan especially drew attention to the subject, set up "infant dispensaries" and advised on the care of infants.

The Foundling Hospital, aimed at stopping the exposure, desertion and murder of infants, was established by Captain Thomas Coram in 1739. The financial difficulties of the hospital, the great demand for places and the terrible records of the deaths of children in the Bills of Mortality induced the Governors, of whom Jonas Hanway was one, to appeal to Parliament for help. From June 1756 to Ladyday 1760 the Hospital received all children brought to it, the cost being defrayed by a Treasury grant. After that it reverted to a private charity. Hanway also inspired the important Act of 1767 which boarded out parish children in London with carefully selected cottagers in the country. Howlett [13] estimated that the London burials were reduced by 2,240 in the first year and, that, allowing for the children who returned to London and died there, the annual average reduction in the London burials was 2,100.

Lettsom and others also advocated improved standards of nutrition for the population at large, and urged the restriction of or abolition of spirit drinking, which was then a cause of high mortality and a blot on our national civilization. The College of Physicians and numerous grand juries and sessions petitioned Parliament to impose restrictions on spirit drinking, and, as a result, a series of Gin Acts were passed which diminished the evil to a certain extent.

INDUSTRIAL HYGIENE

The true father of industrial hygiene was Bernardino Ramazzini, Professor of Medicine in Modena University. About 1700 he published the result of his investigations in a work entitled *The Diseases of Artificers, which in their particular Callings they are most liable to, with the Method of avoiding them and their cure.* This was translated into English by Robert James, M.D., of *Fever Powders* fame in 1746.

The industrial changes in England during the latter half of this century mark the beginnings here of the study of the prevention of diseases of occupation. Medical practitioners could not help being concerned with the lowered physique, the increased amount of disease, the particular manifestations of disease, the higher mortality especially amongst women and children, and the malnutrition and crippling shown by persons employed in the new industries. In the eighteenth century the English

pioneers in this subject were Aiken, Thomas Percival and Ferriar, who formed with others a voluntary Board of Health to direct official and public attention to prevention of these evils.

A well-known example of industrial poisoning is Sir George Baker's investigation of lead colic derived from Devonshire cider. When lead was eliminated from the manufacturing process colic and palsies ceased.

JOHN HUNTER AND EDWARD JENNER

Our concern here is with the practitioners whose assembled work was advancing preventive medicine; and we have no leisure to dwell on the simultaneous advances made in medicine and surgery and in science generally. Yet we must pause for a moment to discern the form of a great surgeon, as Reynolds painted him, clad in red-purple velvet and pondering on the many problems that filled his inquiring mind. John Hunter, largely self-taught, devoted his life and much of his hardly-earned fees to comparative anatomy and experimental pathology and surgery. He elevated the empiricism of surgery into a science and his fame is eternal. His teaching influenced preventive medicine, and to his pupil, Edward Jenner, mankind owes the means of avoiding smallpox and the introduction of the practice of immunity.

The early years of the eighteenth century had seen the adoption of inoculation for the smallpox from Turkey, but this did not prevent the disease, as by cross-infection it increased its incidence, if not its mortality. Jenner did not discover vaccination, but he showed that cowpox was inoculable on man, could be transferred from man to man and that vaccinia protected man from smallpox. The ravages of smallpox prior to the introduction of vaccination were fearful. In London, alone, the Bills of Mortality continued to show to the end of the eighteenth century an average of 1,800 to 2,000 deaths from smallpox annually.

The eighteenth century marks a great advance in investigation and knowledge. The increase in medical epidemiology was already mainly responsible for a more rapid fall in the death-rate. "With all its faults the later Eighteenth Century was a period of improved science, cleanliness and humanity", writes Professor G. M. Trevelyan [6]. Later the laws of hygiene and social welfare were violated in the abrupt transition from rural to industrial England.

THE INFANCY OF STATE MEDICINE

It is apparent from our review of early Preventive Medicine that State Medicine was in its infancy when Queen Victoria ascended the throne in 1837. The reforming vision of Sir Thomas More in public health had long since departed from Councils of State, and the discoveries in the prevention of disease made in the eighteenth century were not as yet applied to national needs. Not that Governments ignored their responsibility for combating disease and preserving the health of His Majesty's subjects in times of dire necessity. As examples of such concern the edicts of Henry VIII and James I against plague and the steps taken by the City of London and the College of Physicians to combat the Great Plague may be cited. In 1720, Dr. Richard Mead in response to an appeal from the Secretary of State made under the threat of an attack of Levantine plague, which was spreading in the South of France, published his *Short Discourse Concerning Pestilential Contagion, and the Methods to be Used to Prevent It.* This not only advised what precautions might be taken for the public safety if plague spread to England, but advocated the setting up of a Council of Health entrusted with all requisite powers. The threatened danger passed and the Government of George I's day did not establish a Ministry of Health.

To take another instance, the Dissolution of the Monasteries, in spite of More's protests, involved the abolition of the hospitals maintained by the monks. Towards

William Smellie, a Scot, who had learned his midwifery in Paris, settled in London, and as practitioner, teacher and writer advanced knowledge of his subject. He elevated the status of the man-midwife; introduced forms of technique for the measurement of the pelvis, safe use of the forceps, diagnosis and treatment of *placenta prævia*, and improved modes of version. Another Scot, William Hunter, was primarily an anatomist, but he was also a practising obstetrician. His methods were conservative, but they were eminently sound. Hunter's pupil, Charles White of Manchester, in his excellent treatise, *On the Management of Pregnant and Lying-in Women and the means of curing but more especially of preventing the principal disorders to which they are liable*, published in 1773, dealt with the general management and hygiene of childbirth, ante-natal supervision, and the cause and prevention of puerperal fever. By his hygienic methods—scrupulous cleanliness, fresh air, suitable temperature of the lying-in ward, dietary and disinfection—he claimed that he had never lost a patient from puerperal fever. These three men, Smellie, Hunter and White, so greatly advanced obstetrics that further improvement was impracticable until Simpson discovered chloroform anæsthesia and Lister antiseptic surgery.

Side by side with improvement in maternal mortality can be noted the beginnings of infant welfare in isolated attempts to control the high mortality of infants and children, which amounted in 1730-49 to as much as 74% of children born. Lettsom and Cadogan especially drew attention to the subject, set up "infant dispensaries" and advised on the care of infants.

The Foundling Hospital, aimed at stopping the exposure, desertion and murder of infants, was established by Captain Thomas Coram in 1739. The financial difficulties of the hospital, the great demand for places and the terrible records of the deaths of children in the Bills of Mortality induced the Governors, of whom Jonas Hanway was one, to appeal to Parliament for help. From June 1756 to Ladyday 1760 the Hospital received all children brought to it, the cost being defrayed by a Treasury grant. After that it reverted to a private charity. Hanway also inspired the important Act of 1767 which boarded out parish children in London with carefully selected cottagers in the country. Howlett [13] estimated that the London burials were reduced by 2,240 in the first year and, that, allowing for the children who returned to London and died there, the annual average reduction in the London burials was 2,100.

Lettsom and others also advocated improved standards of nutrition for the population at large, and urged the restriction of or abolition of spirit drinking, which was then a cause of high mortality and a blot on our national civilization. The College of Physicians and numerous grand juries and sessions petitioned Parliament to impose restrictions on spirit drinking, and, as a result, a series of Gin Acts were passed which diminished the evil to a certain extent.

INDUSTRIAL HYGIENE

The true father of industrial hygiene was Bernardino Ramazzini, Professor of Medicine in Modena University. About 1700 he published the result of his investigations in a work entitled *The Diseases of Artificers, which in their particular Callings they are most liable to, with the Method of avoiding them and their cure.* This was translated into English by Robert James, M.D., of *Fever Powders* fame in 1746.

The industrial changes in England during the latter half of this century mark the beginnings here of the study of the prevention of diseases of occupation. Medical practitioners could not help being concerned with the lowered physique, the increased amount of disease, the particular manifestations of disease, the higher mortality especially amongst women and children, and the malnutrition and crippling shown by persons employed in the new industries. In the eighteenth century the English

pioneers in this subject were Aiken, Thomas Percival and Ferriar, who formed with others a voluntary Board of Health to direct official and public attention to prevention of these evils.

A well-known example of industrial poisoning is Sir George Baker's investigation of lead colic derived from Devonshire cider. When lead was eliminated from the manufacturing process colic and palsies ceased.

JOHN HUNTER AND EDWARD JENNER

Our concern here is with the practitioners whose assembled work was advancing preventive medicine; and we have no leisure to dwell on the simultaneous advances made in medicine and surgery and in science generally. Yet we must pause for a moment to discern the form of a great surgeon, as Reynolds painted him, clad in red-purple velvet and pondering on the many problems that filled his inquiring mind. John Hunter, largely self-taught, devoted his life and much of his hardly-earned fees to comparative anatomy and experimental pathology and surgery. He elevated the empiricism of surgery into a science and his fame is eternal. His teaching influenced preventive medicine, and to his pupil, Edward Jenner, mankind owes the means of avoiding smallpox and the introduction of the practice of immunity.

The early years of the eighteenth century had seen the adoption of inoculation for the smallpox from Turkey, but this did not prevent the disease, as by cross-infection it increased its incidence, if not its mortality. Jenner did not discover vaccination, but he showed that cowpox was inoculable on man, could be transferred from man to man and that vaccinia protected man from smallpox. The ravages of smallpox prior to the introduction of vaccination were fearful. In London, alone, the Bills of Mortality continued to show to the end of the eighteenth century an average of 1,800 to 2,000 deaths from smallpox annually.

The eighteenth century marks a great advance in investigation and knowledge. The increase in medical epidemiology was already mainly responsible for a more rapid fall in the death-rate. "With all its faults the later Eighteenth Century was a period of improved science, cleanliness and humanity", writes Professor G. M. Trevelyan [6]. Later the laws of hygiene and social welfare were violated in the abrupt transition from rural to industrial England.

THE INFANCY OF STATE MEDICINE

It is apparent from our review of early Preventive Medicine that State Medicine was in its infancy when Queen Victoria ascended the throne in 1837. The reforming vision of Sir Thomas More in public health had long since departed from Councils of State, and the discoveries in the prevention of disease made in the eighteenth century were not as yet applied to national needs. Not that Governments ignored their responsibility for combating disease and preserving the health of His Majesty's subjects in times of dire necessity. As examples of such concern the edicts of Henry VIII and James I against plague and the steps taken by the City of London and the College of Physicians to combat the Great Plague may be cited. In 1720, Dr. Richard Mead in response to an appeal from the Secretary of State made under the threat of an attack of Levantine plague, which was spreading in the South of France, published his *Short Discourse Concerning Pestilential Contagion, and the Methods to be Used to Prevent It.* This not only advised what precautions might be taken for the public safety if plague spread to England, but advocated the setting up of a Council of Health entrusted with all requisite powers. The threatened danger passed and the Government of George I's day did not establish a Ministry of Health.

To take another instance, the Dissolution of the Monasteries, in spite of More's protests, involved the abolition of the hospitals maintained by the monks. Towards

William Smellie, a Scot, who had learned his midwifery in Paris, settled in London, and as practitioner, teacher and writer advanced knowledge of his subject. He elevated the status of the man-midwife; introduced forms of technique for the measurement of the pelvis, safe use of the forceps, diagnosis and treatment of *placenta prævia*, and improved modes of version. Another Scot, William Hunter, was primarily an anatomist, but he was also a practising obstetrician. His methods were conservative, but they were eminently sound. Hunter's pupil, Charles White of Manchester, in his excellent treatise, *On the Management of Pregnant and Lying-in Women and the means of curing but more especially of preventing the principal disorders to which they are liable*, published in 1773, dealt with the general management and hygiene of childbirth, ante-natal supervision, and the cause and prevention of puerperal fever. By his hygienic methods—scrupulous cleanliness, fresh air, suitable temperature of the lying-in ward, dietary and disinfection—he claimed that he had never lost a patient from puerperal fever. These three men, Smellie, Hunter and White, so greatly advanced obstetrics that further improvement was impracticable until Simpson discovered chloroform anæsthesia and Lister antiseptic surgery.

Side by side with improvement in maternal mortality can be noted the beginnings of infant welfare in isolated attempts to control the high mortality of infants and children, which amounted in 1730-49 to as much as 74% of children born. Lettsom and Cadogan especially drew attention to the subject, set up "infant dispensaries" and advised on the care of infants.

The Foundling Hospital, aimed at stopping the exposure, desertion and murder of infants, was established by Captain Thomas Coram in 1739. The financial difficulties of the hospital, the great demand for places and the terrible records of the deaths of children in the Bills of Mortality induced the Governors, of whom Jonas Hanway was one, to appeal to Parliament for help. From June 1756 to Ladyday 1760 the Hospital received all children brought to it, the cost being defrayed by a Treasury grant. After that it reverted to a private charity. Hanway also inspired the important Act of 1767 which boarded out parish children in London with carefully selected cottagers in the country. Howlett [13] estimated that the London burials were reduced by 2,240 in the first year and, that, allowing for the children who returned to London and died there, the annual average reduction in the London burials was 2,100.

Lettsom and others also advocated improved standards of nutrition for the population at large, and urged the restriction of or abolition of spirit drinking, which was then a cause of high mortality and a blot on our national civilization. The College of Physicians and numerous grand juries and sessions petitioned Parliament to impose restrictions on spirit drinking, and, as a result, a series of Gin Acts were passed which diminished the evil to a certain extent.

INDUSTRIAL HYGIENE

The true father of industrial hygiene was Bernardino Ramazzini, Professor of Medicine in Modena University. About 1700 he published the result of his investigations in a work entitled *The Diseases of Artificers, which in their particular Callings they are most liable to, with the Method of avoiding them and their cure.* This was translated into English by Robert James, M.D., of *Fever Powders* fame in 1746.

The industrial changes in England during the latter half of this century mark the beginnings here of the study of the prevention of diseases of occupation. Medical practitioners could not help being concerned with the lowered physique, the increased amount of disease, the particular manifestations of disease, the higher mortality especially amongst women and children, and the malnutrition and crippling shown by persons employed in the new industries. In the eighteenth century the English

THE NEW HUMANITY AND THE SOCIAL REVOLUTION

It is recognized but insufficiently emphasized how material and general progress, as exemplified by new inventions and economic prosperity have increased the difficulties of public health reform. In the early part of the eighteenth century (1701-1759) England was an agricultural and pastoral country, which was producing a steadily decreasing surplus of grain, a surplus which was being exported and sold abroad. In this same century, as we have seen, there was an accumulating rise of new scientific knowledge as to the causes and preventabilities of different kinds of disease; and the country under the teaching of the "new humanity", whose prophets were the religious revivalists, John and Charles Wesley and George Whitefield and the practical philanthropists, Oglethorpe and John Howard, had advanced in the principles and practice of politics and sociology. Great Britain had, in fact, in the eighteenth century, begun a new national life with higher conceptions of political good, and preventive medicine would have had a much easier task in improving the health of a nation, which had continued to live chiefly in rural surroundings. The "new humanity" joined with the rising science of organized preventive medicine would have made giant strides in the improvement of national health had social and economic conditions remained as they were during the first half of the eighteenth century. There was, as has been said, a perceptible improvement. This is indicated by the fact that in the single reign of George III (1760-1820) the population of Great Britain rose from about seven and a half to fourteen millions. This unexampled rate was partly due to earlier marriages and an increase in the crude birth-rate, partly due to an improved standard of living, but mainly due to the more rapid fall in the death-rate which in turn depended on the increase in medical knowledge. Then came the discovery of steam and the harnessing of mechanical power to the service of man, which brought about the industrial revolution. This added greatly to the national wealth. To the superficial observer it was certainly progress to see the land, especially the north of England, studded with new factories employing a vast population of workers—men, women and children—to read of the large exports of iron, cotton and coal and to find Britain's merchant ships riding the seas in all four quarters of the globe. But from the aspect of national health it was not progress, because no attention was paid to the laws of hygiene and social welfare in the abrupt transition from rural to industrial England [9].

Towards the close of the eighteenth century the agricultural districts ceased to be adequate for the needs of the people and it became necessary to import wheat and other bread-stuffs. A much smaller acreage of land was under cultivation, because the tillers of the soil left the rural districts and flocked into the already congested towns. This process of migration was accentuated by an enforced migration from rural to urban centres due to the Enclosure Acts, which deprived the independent yeoman peasantry of their ancient rights as freeholders in order that large estates and farms might be increased. The intention was to augment the food supply of the country for the increasing population. In effect it depopulated the countryside; and, along with voluntary migration, it favoured overcrowding, disease and epidemics, and assisted to give England and Wales the problem of the slums, which only in comparatively recent times the State has been able to assail by its housing and overcrowding legislation.

Over and above all this, there were the terrible conditions of women and child slavery in the mines and factories. The horrors of the Factory System as it affected children are almost indescribable. The hours during which these unhappy helpless beings worked were excessive; they were harshly and sometimes cruelly treated; the time allowed for rest and meals was utterly insufficient; for education, moral and religious training and health no time at all was allowed. All day the iron wheels were droning and turning, grinding out the lives of little children, and the end of the seventeenth century Macaulay [7] states there was not then, in the whole realm, a single infirmary maintained by voluntary contribution. "Even in the capital the only edifices open to the wounded were the two ancient hospitals of Saint Thomas and Saint Bartholomew", preserved by the resolute action of the citizens of London in the sixteenth century. Yet after the naval Battle of La Hogue in 1692, fifty surgeons, plentifully supplied with instruments, bandages and drugs were sent down in all haste from London to Portsmouth at government expense, and Queen Mary, the wife of William III, gave orders that in the two London hospitals arrangements should be made at the public charge for the reception of patients from the Fleet, a precedent for the Emergency Hospital Service of the last war. The foundation of Greenwich Hospital for disabled seamen also dates from William and Mary's time. In the eighteenth century philanthropy caused many of the great London hospitals and a large number of provincial hospitals to be built, and there were certain workhouse infirmaries for the destitute poor.

The attitude of successive governments towards preventive medicine was much that of the ordinary man towards his private doctor. The government only sought medical advice from the Royal College of Physicians or individual leaders of the profession for the health of the community in cases of emergency, or when pestilence had appeared or was threatening. As Mead did, the advisers, in addition to necessary measures to deal with the immediate situation, not infrequently recommended some form of permanent state organization to maintain the public health, but the advice was ignored as soon as the emergency had passed.

The Fighting Services had displayed greater perspicacity. Sir John Pringle (1707-1782) by his work on *Diseases of the Army* had begun hygienic reform in the British Army, and Dr. James Lind and Sir Gilbert Blane were abolishing scurvy and advocating the study of hygiene in the Royal Navy.

The high incidence of disease and mortality in the civilian population for the most part went unheeded. Cholera appeared in the United Kingdom from 1831 to 1833, the first invaded port being Sunderland. A consultative Board of Health was set up under the Presidency of Sir Henry Halford, then President of the Royal College of Physicians, but its chief functions were restricted to the giving of medical advice as it had no executive authority. The advent of this new pestilence gave rise to an uneasy feeling that precautions taken after the introduction of disease instead of before the event were not altogether satisfactory.

Simon [8] sums up the situation in the following words:

> "Thus in 1830, when William the Fourth began his reign, and equally in 1837 when the reign ended, the new knowledge was virtually unrecognized by the Legislature. The Statute Book contained no general law of sanitary intention, except (so far as this deserves to be counted an exception) the Act providing for Quarantine, under which well-intentioned but futile Act, the Lords of the Council were supposed to be always on the look-out for transmarine dangers of pestilence, and could make pretence of resisting such dangers. Against smallpox, Parliament used annually to vote £2,000 to support a National Vaccine Board which had a few vaccinating stations in London, and furnished the public with vaccine lymph. Outside these two matters, the Central Government had nothing to say in regard to the Public Health, and Local Authorities had but the most indefinite relation to it. Various important towns had their special Improvement Acts for certain purposes: but among the purposes Health had hardly yet begun to stand on its own merits."

But now, in addition to the threat of pestilence, important social influences were in operation which were to break down the barriers hitherto interposed against national health reform. It will not be irrelevant to examine these influences and to see how they affected public opinion.

Jeremy Bentham (1748-1832) by his personality and doctrine, his breadth of view and prodigious range of knowledge left his mark alike on morals and legislation. "He had been in early life the friend of Adam Smith, the Wesleys, Mirabeau and William Pitt; later James Mill, Samuel Romilly, and Etienne Dumont were his comrades and disciples, while in the evening of his life Chadwick and Dr. Southwood Smith resided with him at his hermitage at Queen's Gate, Westminster, and acted as secretaries during the last three years of the octogenarian sage" [12].

Such were the influences at work which helped to constitute a powerful body of public opinion, forceful and articulate. By 1837 Parliament had instituted a number of substantial political reforms. Slavery had been abolished in the British colonies though not as yet in the factories and mines in England and Scotland; still, factory legislation had been initiated. The Roman Catholics had been emancipated; there was a new Poor Law, a certain amount of municipal reform had been effected; and the Registration of Births, Deaths and Marriages heralded the national vital statistics. Mechanical transport had come to complicate existence with steamboats, the steam engine and the beginnings of a railway system.

GRAVE IMPAIRMENT OF NATIONAL HEALTH

The Industrial Revolution, as we have seen, changed the character of England. Driven from their small-holdings by the Enclosure Acts, the peasants flocked to be employed in the new factories, and the towns in the industrial districts had to grow rapidly to accommodate them. This increased and sudden urbanization of the people in the late eighteenth and early nineteenth centuries created most serious sanitary problems. In the hasty building of the new industrial towns there was no idea of town planning and little thought for the future. The workers' environment was deplorable. In many cases the elementary rules of building construction were ignored in erecting houses. No attention was paid to suitability of soil, site, conveniences, curtilage, water supply and treatment of sewage. The houses were crowded together, built badly with indifferent materials, damp, badly lighted and ventilated, and often placed back to back. These houses being of small capacity the people inhabiting them were grossly overcrowded. Not only did the conditions in the mines and factories promote degradation, crippling and disease, but the home conditions of the workers were even worse. Dirt and disease, malnutrition and sometimes starvation prevailed, and these horrible conditions were aggravated by the increasing density of the population. In 1838 a joint report by Dr. Neil Arnott and Dr. James Phillips Kay and a report by Dr. Southwood Smith to the Poor Law Commissioners gave a terrible picture of the ravages inflicted by infectious disease in London at that time. They showed that out of 77,000 persons (in- and out-door paupers) 14,000 were attacked by fever, one-fifth part of the whole, and that out of the 14,000 attacked nearly 1,300 died. London provided the most glaring examples of this kind, but infectious diseases then rioted uncontrolled to a large extent throughout England. The chief diseases appear to have been typhus and typhoid fevers, cholera, smallpox, scarlet fever and measles.

To sum up, wretchedness, sickness and mortality prevailed among the working population. Infectious diseases wrought havoc among all classes of the community, for not infrequently fever was carried from the hovel to the mansion. The economic loss to the nation caused by ill-health must have been great.

CONCLUSION

It was now high time for the knowledge of hygiene and of the prevention of disease, already acquired by the medical profession, to be applied to the crying needs of the nation. The hour of deliverance had struck, and pioneers in both health and social reform were at hand. The work of Edwin Chadwick, Southwood squandering in the process the health and vitality of a considerable portion of the nation. As Dean Spence [10] wrote:

> "The poor little ones laboured like beasts of burden, and toiling on the long week through in their subterranean workshops, scarcely ever caught a sight of the sunshine during the six days of unremitting work. The seeds of many diseases were thus early sown. Many became permanently sickly, and not a few died."

Evil has many descendants and the appalling conditions which prevailed before reform came inevitably weakened healthy stocks and national stamina.

The reform came only by stages. In 1802 the first Sir Robert Peel, inspired by the medical findings of Percival and his associates, carried through Parliament his "merciful Act", which provided in some degree for care and education of these children. In 1819 he succeeded in obtaining another Act, which forbade children *under nine years of age* working in a cotton factory, while no young person under sixteen was to be allowed to work *more than twelve hours a day*, exclusive of meals. Further and more comprehensive legislation was attempted in 1830-31, but even then was sadly inadequate, until later legislation promoted by Lord Ashley, afterwards the seventh Earl of Shaftesbury, resulted in the Factory Acts.

With the Industrial Revolution, its benefits and its evils, came a sweeping change in the social hierarchy. The established authority of the landed classes was threatened by a rising middle class, rich in accumulated commercial wealth, and by the increasing population of workers—an urban population, which from the beginning of the nineteenth century grew at the rate of 30% every ten years. The workers agitated for lightening of taxation, bread at fixed price, reform of justice, universal suffrage and annual parliaments. The new commercial classes and the inhabitants of the rising towns demanded representation in Parliament and the abolition of the rotten boroughs. The Whigs adopted a policy of reform with a limited franchise and the artisans with a sound political instinct supported this as an instalment of more complete reform. In 1832 the Reform Bill was passed and opened a new era in English History. The will of the people had prevailed against a tradition of four hundred years of restriction and privilege.

As always happens in a revolutionary epoch, countless schemes were now mooted for the improvement of the human race and for the well-being of the British people in particular. They ranged from extreme views based on Thomas Paine's *Rights of Man* and communistic theories fathered by the Jacobins of the French Revolution to the Chartist movement which united radicals, socialists, trade unionists and the considerable women's suffrage clubs in a pledge to put aside all other questions until they had won the vote. These movements died away, but their very existence indicated that the mass of the people had deep-seated grievances to redress and could now unite to voice them [11].

In the new society which the Industrial Revolution had called into being the manufacturers and the workers demanded social reforms and were supported by scientists like Davy, Herschel, Watt and Stephenson; religious philanthropists, such as Zachary Macaulay, Clarkson, Wilberforce; and the secular reformers, James Mill, Romilly, Mackintosh, Huskisson, Jeremy Bentham and others. They ventilated such questions as universal suffrage, the ballot, reform of Parliament, freedom of the Press, just and equal laws and alteration of the savage and harsh penal code.

Of outstanding influence on the future of public health were the doctrines of the philosopher, Jeremy Bentham, who proclaimed that the end of all government must be utility, or the good of the governed. "The greatest happiness of the greatest number", as he phrased it, though the words were originally used by Joseph Priestley to produce anæsthesia adequate for dental extractions in a number of patients, although by ill-luck Wells's public demonstration was a failure.

In view of Wells's experience it is not at all surprising that Morton should have chosen sulphuric ether as his anæsthetic agent. Michael Faraday in 1818 had drawn attention to the similarity of the physiological effect produced by nitrous oxide gas and by ether vapour when inhaled, and in the eighteen-forties this similarity was widely recognized. Indeed Long had already chosen between these two agents.

During his preliminary trials of etherization Morton gleaned from the scientist C. T. Jackson (his former chemistry tutor) one very important hint—to use rectified ether, not that ordinarily sold. In devising an inhaler to be used at the demonstration arranged for October 16, Morton had the active help of another able Bostonian, the physician Augustus A. Gould. On the very eve of the demonstration this inhaler had not yet taken final shape, but after working with Gould far into the night, Morton next morning took the finished design to an instrument maker and remained supervising the making of the inhaler until the last possible moment. He arrived late in the operating theatre of the Massachusetts General Hospital with his inhaler untried.

John Collins Warren, the surgeon on that historic occasion, described how the patient (a young man from beneath whose jaw a tumour was to be removed) after inhaling for four or five minutes, appeared to be asleep. He remained so until the tying of the veins "during which", said Warren, "he began to move his limbs, cry out, and utter extraordinary expressions. These phenomena led to a doubt of the success of the application; and in truth I was not satisfied myself until I had, soon after the operation and on various other occasions, asked the question whether he had suffered pain. To this he always replied in the negative, adding, however, that he knew of the operation, and comparing the stroke of the knife to that of a blunt instrument passed roughly across his neck".

The apparatus which Morton had used consisted of a two-necked glass globe containing an ether-soaked sponge; in one neck was an inspiratory flap-valve, the other neck ended in a tube which the patient held in his lips (the outside of his mouth being cupped by a flange and his nostrils being pinched together by a bystander). Behind the mouth-tube was an expiratory valve, guarded by a metal cover. A fortuitous but important advantage lay in the fact that the administrator held this inhaler in his palm, and the natural warmth facilitated vaporization of the ether.

After Morton's demonstration various distinguished Bostonians who had witnessed it, hastened to send word of etherization to colleagues not only elsewhere in America but in Europe. Among the first to receive the news here was the American-born and educated Francis Boott, a physician living in Gower Street, London.

Boott immediately set about testing etherization for himself and, on December 19, 1846, he and a dentist named Robinson, after administering ether vapour to a certain Miss Lonsdale, extracted from her mouth "a firmly fixed molar tooth" without, as he said, "the least sense of pain, or the movement of a muscle. The whole process of inhalation, extracting and waking, was over in three minutes".

Boott also wrote to Robert Liston, Professor of Surgery in the University of London, and on Monday, December 21, Liston operated painlessly on two patients who inhaled ether from an apparatus improvised by Squire, of Oxford Street. One patient had his leg amputated at the thigh, the other had a toenail removed.

Squire's large, valved, sponge-filled glass inhaler was intended to stand by itself. A long, narrow tube led the ether-air mixture to a flanged mouth-tube, and the patient's nostrils were closed by a clip. This was the type of inhaler widely adopted both in the British Isles and on the European Continent during the early days of ether anæsthesia.

Smith, John Simon and Lord Shaftesbury created an administrative system of State Medicine which has achieved a position in the world second to none.

That golden story lies outside the purview of this Address. In the time at my disposal, I have tried to show you the beginnings of English Preventive Medicine, how physicians, surgeons and general practitioners—especially in the eighteenth century—sought painfully and carefully for the causes of disease and worked out measures of prevention. They worked alone for the most part. Many of them never saw the result of their labours. "Some there be which have no memorial."

But when philanthropists, humanitarians and administrators looked with sick and sorry hearts on the disease and many evils wrought by the Industrial Revolution, they turned to these enlightened members of the medical profession and found there was an answer to the social problems of the age. Thus English State Medicine was born. The administrators took the credit, often with justice, but the medical pioneers did the work, inspired appropriate legislation and made it practicable. That, however, is of little moment. Ours is characteristically a self-denying profession, and sees its reward in the conquest of disease, a greatly reduced mortality and the alleviation of pain and suffering.

Finis coronat opus.

The Development of Inhalation Anæsthesia in the Second Half of the Nineteenth Century

By Barbara Duncum, Ph.D.

On this day one hundred years ago, William Thomas Green Morton, a dentist of Boston, in the United States of America, conclusively demonstrated what the Englishman, Henry Hill Hickman, had stoutly but unavailingly maintained during the eighteen-twenties, namely that surgical anæsthesia by inhalation was a practical proposition. That the time was now ripe for such a demonstration is shown by the fact that four years earlier, in 1842, and in the succeeding years, C. W. Long had performed minor operations painlessly on patients to whom he had administered the vapour of sulphuric ether. Morton was unaware of this, but he did know that his former partner, Horace Wells, had used nitrous oxide during the winter of 1844-5 to produce anæsthesia adequate for dental extractions in a number of patients, although by ill-luck Wells's public demonstration was a failure.

In view of Wells's experience it is not at all surprising that Morton should have chosen sulphuric ether as his anæsthetic agent. Michael Faraday in 1818 had drawn attention to the similarity of the physiological effect produced by nitrous oxide gas and by ether vapour when inhaled, and in the eighteen-forties this similarity was widely recognized. Indeed Long had already chosen between these two agents.

During his preliminary trials of etherization Morton gleaned from the scientist C. T. Jackson (his former chemistry tutor) one very important hint—to use rectified ether, not that ordinarily sold. In devising an inhaler to be used at the demonstration arranged for October 16, Morton had the active help of another able Bostonian, the physician Augustus A. Gould. On the very eve of the demonstration this inhaler had not yet taken final shape, but after working with Gould far into the night, Morton next morning took the finished design to an instrument maker and remained supervising the making of the inhaler until the last possible moment. He arrived late in the operating theatre of the Massachusetts General Hospital with his inhaler untried.

John Collins Warren, the surgeon on that historic occasion, described how the patient (a young man from beneath whose jaw a tumour was to be removed) after inhaling for four or five minutes, appeared to be asleep. He remained so until the tying of the veins "during which", said Warren, "he began to move his limbs, cry out, and utter extraordinary expressions. These phenomena led to a doubt of the success of the application; and in truth I was not satisfied myself until I had, soon after the operation and on various other occasions, asked the question whether he had suffered pain. To this he always replied in the negative, adding, however, that he knew of the operation, and comparing the stroke of the knife to that of a blunt instrument passed roughly across his neck".

The apparatus which Morton had used consisted of a two-necked glass globe containing an ether-soaked sponge; in one neck was an inspiratory flap-valve, the other neck ended in a tube which the patient held in his lips (the outside of his mouth being cupped by a flange and his nostrils being pinched together by a bystander). Behind the mouth-tube was an expiratory valve, guarded by a metal cover. A fortuitous but important advantage lay in the fact that the administrator held this inhaler in his palm, and the natural warmth facilitated vaporization of the ether.

After Morton's demonstration various distinguished Bostonians who had witnessed it, hastened to send word of etherization to colleagues not only elsewhere in America but in Europe. Among the first to receive the news here was the American-born and educated Francis Boott, a physician living in Gower Street, London.

Boott immediately set about testing etherization for himself and, on December 19, 1846, he and a dentist named Robinson, after administering ether vapour to a certain Miss Lonsdale, extracted from her mouth "a firmly fixed molar tooth" without, as he said, "the least sense of pain, or the movement of a muscle. The whole process of inhalation, extracting and waking, was over in three minutes".

Boott also wrote to Robert Liston, Professor of Surgery in the University of London, and on Monday, December 21, Liston operated painlessly on two patients who inhaled ether from an apparatus improvised by Squire, of Oxford Street. One patient had his leg amputated at the thigh, the other had a toenail removed.

Squire's large, valved, sponge-filled glass inhaler was intended to stand by itself. A long, narrow tube led the ether-air mixture to a flanged mouth-tube, and the patient's nostrils were closed by a clip. This was the type of inhaler widely adopted both in the British Isles and on the European Continent during the early days of ether anæsthesia.

News of surgical anæsthesia reached the Continent, and in particular France, at about the time that it reached Boott in England. Nevertheless it was not adopted there until the New Year. On January 21, 1847, the surgeon J. F. Malgaigne, at a meeting of the Académie de Médecine, in Paris, reported on five cases in which he himself had administered ether. Having no other kind of inhaler, Malgaigne introduced one end of a tube containing ether into his patient's nostril—the other nostril being plugged—and saw to it that inspiration took place through the nose, expiration through the mouth.

It was not only the surgeons who, during the early months of 1847, embarked on the further investigation of anæsthesia. Physiologists, also, carried out experiments with various potentially anæsthetic agents to ascertain individual properties and to establish their mode of action. Prominent in this field of research was the Frenchman, P. J. M. Flourens, who, during February and March 1847, experimented upon animals with sulphuric ether, ethyl chloride, and chloroform. He recorded that anæsthesia acted first upon the cerebrum—affecting the intellectual functions; secondly upon the cerebellum—deranging the equilibrium of movements; then upon the spinal cord—successively inhibiting sensibility and motility; finally upon the medulla oblongata—and when that phase was reached life became extinct.

In England, during February 1847, the physician John Snow also was carrying out experiments on animals. One conclusion he reached was that the anæsthetic agent acted by reducing oxidation in the body to a minimum. For the guidance of clinical administrators (of whom he was already one) Snow divided the progress of anæsthesia into five easily recognizable stages.

Anæsthesia in all its aspects was now Snow's dominant interest and henceforward he was acknowledged as the leading authority. He was quick to realize the shortcomings of inhalers such as Squire's. "When the inhalation of ether was first commenced", he wrote, "the inhalers employed consisted generally of glass vases containing sponge, to afford a surface for the evaporation of the ether. Both glass and sponge being very indifferent conductors of caloric, the interior of the inhalers became much reduced in temperature, the evaporation of ether was very much checked, and the patient breathed air much colder than the freezing point of water, and containing very little of the vapour of ether. On this account, and through other defects in the inhalers [elsewhere Snow mentioned faulty valves and tubing of too narrow bore], the patient was often very long in becoming insensible, and, in not a few cases, he did not become affected beyond a degree of excitement and inebriety."

Attempts to remedy these defects were indeed made early in 1847. Various kinds of valves were tried and inhalers were warmed by immersing them in hot water or by incorporating a warm-water chamber, but these empirical efforts were more often remarkable for ingenuity than for true insight into the problems of ether administration.

Snow was the first to design an inhaler based upon scientific reasoning. He worked upon the known fact that at different temperatures air will take up different amounts of ether vapour. When the inhaler was assembled for use, the metal carrying-case held water at a temperature of 50° F., and in this the ether vaporizing chamber was placed. The chamber contained a spiral baffle-plate to ensure that the air stream drawn in through a valveless tube by the patient came fully in contact with the liquid ether. Wide-bored, flexible tubing led the ether-air mixture to a valved facepiece—the latter an important innovation of Snow's, based upon a valveless facepiece devised by his friend Francis Sibson for anæsthetizing a patient with a facial tic. With the water-bath at 50° F., Snow's inhaler delivered an ether-air mixture containing 30% ether vapour. This mixture could be diluted by turning aside the expiratory flap-valve on the facepiece.

Despite the introduction of this inhaler, the difficulties which most people encountered in using ether made them anxious for some still more manageable means of anæsthetizing. This was supplied in November 1847, by James Young Simpson, Professor of Midwifery at Edinburgh. After testing a number of drugs, Simpson, at the suggestion of David Waldie, Chemist to the Apothecaries Company of Liverpool, tried chloroform. He found it, as he said, "infinitely more efficacious than any of the others", with the added advantage that "no special kind of inhaler or instrument is necessary for its exhibition. A little of the liquid diffused upon the interior of a hollow-shaped sponge, or a pocket-handkerchief, or a piece of linen or paper, and held over the mouth and nostrils, so as to be fully inhaled, generally suffices in about a minute or two to produce the desired effect".

Finding that this was indeed the case, medical men throughout the world immediately discarded ether and adopted chloroform.

Although it was not many weeks before deaths due to chloroform began to occur, such were the difficulties associated with etherization that only in the northern United States, in Lyons and through the Lyonnais example, in Naples, was a return made to its use. The reason for this return was, I think, because the Americans and the surgeons of Lyons had each hit upon a satisfactory method of administration. At the Massachusetts General Hospital, directly it became known that Morton was attempting to obtain a patent, the use of his inhaler was given up, and liquid ether was poured on to a bell-shaped sponge which was then firmly held over the patient's nose and mouth. The method of administering ether from a sponge, or from a sponge placed in the apex of a cone improvised from a folded towel, at once proved so simple and so satisfactory that it persisted in America, largely to the exclusion of other methods, until the end of the nineteenth century and after.

At Lyons, also, the method of etherization originally used there and re-adopted after the death of a patient under chloroform, was still in use in 1900. Liquid ether was poured into a bag, named after its inventor "Roux's *sac*". An air-port in the side could be opened or closed by a stopper. Strings drew the mouth of the bag snugly but not tightly round the patient's nose and mouth, and were then tied behind his head.

By about 1850, anæsthetic practice had assumed certain distinctive characteristics in different parts of the world. At Lyons and in the northern States of America ether was used, as I have just described. The southern States traditionally followed the example of Paris in medical matters; and in Paris chloroform was administered from a folded cloth, according to Simpson's directions. Not only the southern States of America, but the rest of France and indeed the rest of the Continent tended to copy Parisian methods. And in Scotland, of course, Simpson's method reigned supreme. In none of these places was it considered necessary to employ an expert anæsthetist and the task of administration was usually relegated to a junior house surgeon.

But in England a very different state of affairs obtained. Mainly, no doubt, because of John Snow's strong influence, the English almost from the first considered the giving of an anæsthetic to be a specialist's job, and believed that the use of some kind of regulating inhaler safeguarded the patient.

Simple and effective as Simpson's method of chloroform anæsthesia was, the English, by the beginning of 1848, had already devised a number of more or less elaborate chloroform inhalers, and Snow again controlled the anæsthetic mixture by regulating the temperature of the vaporizing chamber by a water-jacket. Snow's portable regulating chloroform inhaler served his contemporaries as a model until the introduction of Clover's chloroform apparatus in 1862. In the latter apparatus (which was itself based upon an experimental inhaler of Snow's) a mixture of 4½% chloroform

News of surgical anæsthesia reached the Continent, and in particular France, at about the time that it reached Boott in England. Nevertheless it was not adopted there until the New Year. On January 21, 1847, the surgeon J. F. Malgaigne, at a meeting of the Académie de Médecine, in Paris, reported on five cases in which he himself had administered ether. Having no other kind of inhaler, Malgaigne introduced one end of a tube containing ether into his patient's nostril—the other nostril being plugged—and saw to it that inspiration took place through the nose, expiration through the mouth.

It was not only the surgeons who, during the early months of 1847, embarked on the further investigation of anæsthesia. Physiologists, also, carried out experiments with various potentially anæsthetic agents to ascertain individual properties and to establish their mode of action. Prominent in this field of research was the Frenchman, P. J. M. Flourens, who, during February and March 1847, experimented upon animals with sulphuric ether, ethyl chloride, and chloroform. He recorded that anæsthesia acted first upon the cerebrum—affecting the intellectual functions; secondly upon the cerebellum—deranging the equilibrium of movements; then upon the spinal cord—successively inhibiting sensibility and motility; finally upon the medulla oblongata—and when that phase was reached life became extinct.

In England, during February 1847, the physician John Snow also was carrying out experiments on animals. One conclusion he reached was that the anæsthetic agent acted by reducing oxidation in the body to a minimum. For the guidance of clinical administrators (of whom he was already one) Snow divided the progress of anæsthesia into five easily recognizable stages.

Anæsthesia in all its aspects was now Snow's dominant interest and henceforward he was acknowledged as the leading authority. He was quick to realize the shortcomings of inhalers such as Squire's. "When the inhalation of ether was first commenced", he wrote, "the inhalers employed consisted generally of glass vases containing sponge, to afford a surface for the evaporation of the ether. Both glass and sponge being very indifferent conductors of caloric, the interior of the inhalers became much reduced in temperature, the evaporation of ether was very much checked, and the patient breathed air much colder than the freezing point of water, and containing very little of the vapour of ether. On this account, and through other defects in the inhalers [elsewhere Snow mentioned faulty valves and tubing of too narrow bore], the patient was often very long in becoming insensible, and, in not a few cases, he did not become affected beyond a degree of excitement and inebriety."

Attempts to remedy these defects were indeed made early in 1847. Various kinds of valves were tried and inhalers were warmed by immersing them in hot water or by incorporating a warm-water chamber, but these empirical efforts were more often remarkable for ingenuity than for true insight into the problems of ether administration.

Snow was the first to design an inhaler based upon scientific reasoning. He worked upon the known fact that at different temperatures air will take up different amounts of ether vapour. When the inhaler was assembled for use, the metal carrying-case held water at a temperature of 50° F., and in this the ether vaporizing chamber was placed. The chamber contained a spiral baffle-plate to ensure that the air stream drawn in through a valveless tube by the patient came fully in contact with the liquid ether. Wide-bored, flexible tubing led the ether-air mixture to a valved facepiece—the latter an important innovation of Snow's, based upon a valveless facepiece devised by his friend Francis Sibson for anæsthetizing a patient with a facial tic. With the water-bath at 50° F., Snow's inhaler delivered an ether-air mixture containing 30% ether vapour. This mixture could be diluted by turning aside the expiratory flap-valve on the facepiece.

Despite the introduction of this inhaler, the difficulties which most people encountered in using ether made them anxious for some still more manageable means of anæsthetizing. This was supplied in November 1847, by James Young Simpson, Professor of Midwifery at Edinburgh. After testing a number of drugs, Simpson, at the suggestion of David Waldie, Chemist to the Apothecaries Company of Liverpool, tried chloroform. He found it, as he said, "infinitely more efficacious than any of the others", with the added advantage that "no special kind of inhaler or instrument is necessary for its exhibition. A little of the liquid diffused upon the interior of a hollow-shaped sponge, or a pocket-handkerchief, or a piece of linen or paper, and held over the mouth and nostrils, so as to be fully inhaled, generally suffices in about a minute or two to produce the desired effect".

Finding that this was indeed the case, medical men throughout the world immediately discarded ether and adopted chloroform.

Although it was not many weeks before deaths due to chloroform began to occur, such were the difficulties associated with etherization that only in the northern United States, in Lyons and through the Lyonnais example, in Naples, was a return made to its use. The reason for this return was, I think, because the Americans and the surgeons of Lyons had each hit upon a satisfactory method of administration. At the Massachusetts General Hospital, directly it became known that Morton was attempting to obtain a patent, the use of his inhaler was given up, and liquid ether was poured on to a bell-shaped sponge which was then firmly held over the patient's nose and mouth. The method of administering ether from a sponge, or from a sponge placed in the apex of a cone improvised from a folded towel, at once proved so simple and so satisfactory that it persisted in America, largely to the exclusion of other methods, until the end of the nineteenth century and after.

At Lyons, also, the method of etherization originally used there and re-adopted after the death of a patient under chloroform, was still in use in 1900. Liquid ether was poured into a bag, named after its inventor "Roux's *sac*". An air-port in the side could be opened or closed by a stopper. Strings drew the mouth of the bag snugly but not tightly round the patient's nose and mouth, and were then tied behind his head.

By about 1850, anæsthetic practice had assumed certain distinctive characteristics in different parts of the world. At Lyons and in the northern States of America ether was used, as I have just described. The southern States traditionally followed the example of Paris in medical matters; and in Paris chloroform was administered from a folded cloth, according to Simpson's directions. Not only the southern States of America, but the rest of France and indeed the rest of the Continent tended to copy Parisian methods. And in Scotland, of course, Simpson's method reigned supreme. In none of these places was it considered necessary to employ an expert anæsthetist and the task of administration was usually relegated to a junior house surgeon.

But in England a very different state of affairs obtained. Mainly, no doubt, because of John Snow's strong influence, the English almost from the first considered the giving of an anæsthetic to be a specialist's job, and believed that the use of some kind of regulating inhaler safeguarded the patient.

Simple and effective as Simpson's method of chloroform anæsthesia was, the English, by the beginning of 1848, had already devised a number of more or less elaborate chloroform inhalers, and Snow again controlled the anæsthetic mixture by regulating the temperature of the vaporizing chamber by a water-jacket. Snow's portable regulating chloroform inhaler served his contemporaries as a model until the introduction of Clover's chloroform apparatus in 1862. In the latter apparatus (which was itself based upon an experimental inhaler of Snow's) a mixture of 4½% chloroform vapour in air was prepared and stored in a reservoir bag from which the patient inhaled it through a facepiece and tubing.

By 1864 the occurrence of deaths directly attributable to chloroform anæsthesia had become so formidable that a committee of investigation was appointed by the Royal Medical and Chirurgical Society. The majority of anæsthetists had long hoped for, and a few men, notably Snow, had actively sought some agent which would combine the convenience of chloroform anæsthesia with the avowedly greater safety of ether. It was by then evident that no such perfect anæsthetic would readily be found. So, chiefly through Joseph Thomas Clover (who, since Snow's death in 1858, had quietly become recognized as the new leader of the profession) the committee carried out a number of experiments with the two agents of proved worth—ether and chloroform. These experiments demonstrated anew that chloroform was the more dangerous because it acted directly upon the heart, whereas ether acted first upon the respiration, and in the event of an overdose the patient might be revived by artificial respiration. Despite these findings the committee, as it stated, concurred "in the general opinion which in this country has led to the disuse of ether as an inconvenient anæsthetic". To avoid the dilemma, the committee suggested that both agents should be used together in the hope that each might counteract the disadvantages of the other. The mixture particularly recommended was Harley's A.C.E., 1 part alcohol, 2 parts chloroform, 3 parts ether.

After the committee's report a new and more flexible attitude towards anæsthetic questions is perceptible in English practice, for it was at last beginning to be realized that no single agent could be expected completely to satisfy every requirement. This process of realization was hastened in 1868 by the introduction of nitrous oxide anæsthesia into English dental practice.

Nitrous oxide anæsthesia had been reintroduced into American dental practice in 1863, by G. Q. Colton, the itinerant, pseudo-scientific lecturer, whose demonstration of the properties of the gas at Hartford, Connecticut, in 1844, had been the cause of Wells's trial of its anæsthetic effect. During the International Exhibition in Paris, in 1867, Colton taught the American-born, Parisian dentist, T. W. Evans, to make and use the gas. In the following year, Evans made a special journey to London in order to pass on his knowledge to the chloroformists.

The Americans administered nitrous oxide either from a large rubber bag previously filled with it, or by letting the patient draw it directly from the generating apparatus through a mouthpiece and tubing. The English, led by Clover and by the dental surgeon, Alfred Coleman, were not slow in improving upon these methods. In the typical English apparatus, first put together in 1868 and retained in use during the next twenty-five years, the patient inhaled through a facepiece with a cushioned rim to ensure an airtight fit. (Colton had emphasized that the gas must be administered free from air.) Wide-bored tubing linked the facepiece to a reservoir bag, which had been added to the apparatus by W. A. N. Cattlin, a dentist. Narrow tubing connected with a cylinder of gas, which the firms of Barth and of Coxeter had succeeded in compressing on a commercial scale.

Although on the Continent the Franco-Prussian War seriously interfered with the adoption and development of nitrous oxide anæsthesia, an important contribution to its use was made by the French physiologist, Paul Bert. In 1878, Bert pointed out that so long as patients were forced to inhale undiluted nitrous oxide, anæsthesia would be complicated by asphyxia. He suggested that operations should be conducted in a chamber in which the pressure could be increased to two atmospheres. This would allow 50% of air or oxygen to be administered with the nitrous oxide. Bert's suggestion was adopted by a few surgeons, and for a year or two a mobile, positive pressure, operating theatre—Bert's anæsthetic car—plied between the hospitals of

Paris. In 1883, however, Bert proposed the simpler procedure of administering a mixture of oxygen and nitrous oxide at normal pressure. This procedure had already been put into practice in 1868, by Edmund Andrews, of Chicago. Curiously enough, neither Andrews's colleagues nor Bert's showed any great interest at the time; but indirectly through Bert's suggestion, nitrous oxide and oxygen anæsthesia was developed by the Russian obstetrician, Klikowitsch, and independently by various German and Austrian dentists—notably Hillischer of Vienna. It was through Hillischer's example that the English specialist anæsthetist, Frederic William Hewitt, during the last decade of the nineteenth century, was led to make very great improvements in the technique of nitrous oxide and oxygen anæsthesia.

In 1872, another American came to England bent on converting the chloroformists —this time to the use of ether. He was B. J. Jeffries, an ophthalmic surgeon from Boston, and the primary reason for his visit was an ophthalmological congress in London, at which he read a paper on the towel and sponge method of etherization. "Now if the patient is warned that ether will choke him", said Jeffries, "and told when this occurs to take long breaths to relieve it, and not struggle and endeavour to push away the sponge, many will go to sleep quietly and without trouble to themselves or the surgeon. . . . When the patient, whether old or young, struggles, and asks for a respite and fresh air, do not yield. Hold them down by main force if necessary, and, at any rate, keep the sponge tight over the mouth and nose till they finally take long breaths and then go off into ether sleep." Afterwards Jeffries gave demonstrations at several London hospitals, and though his uncompromising technique must have startled the cautious chloroformists, they readily admitted its success. By the spring of 1873 ether was once more in general use in this country, but already regulating inhalers were ousting the sponge and cone from use.

Of the various ether inhalers designed during the eighteen-seventies, two are outstanding—Ormsby's, and Clover's portable regulating inhaler. Both were described in the medical journals early in 1877. Clover himself, however, continued to prefer his apparatus for combined nitrous oxide and ether anæsthesia, on which he had begun to work as early as 1871, and which took its final form in 1876.

It seems probable that, as in the case of nitrous oxide anæsthesia, the troubled times following the Franco-Prussian War hindered the spread of the revived use of ether from England to the Continent. In 1877, in Geneva, however, the surgeon, Gustave Julliard, after a death from chloroform had occurred in his hands, abandoned the use of that anæsthetic and adopted etherization. He administered ether from a large face-mask, gauze lined but completely covered outside by waxed fabric impermeable to air. The use of this method gradually advanced northward and by 1890 had reached Tübingen in South Germany.

During the eighteen-eighties the surgeon Oscar Wanscher, of Copenhagen, also began to use ether—both rectally (a method originally introduced by the Russian surgeon Pirogoff, in 1847) and by inhalation. The inhaler which he used was a modification of Ormsby's. In 1890, the gynæcologist Landau, in Berlin, adopted Wanscher's method of inhaling ether. But in Germany as a whole, chloroform was exclusively used and was generally administered either from some variant of the small, open mask introduced into practice by Thomas Skinner, of Liverpool, in 1862, or from the inhaler originally designed by F. E. Junker in 1867, for administering B. W. Richardson's then new anæsthetic, bichloride of methylene. Junker, who was a Doctor of Medicine of Vienna, was at the time physician at the Samaritan Free Hospital in London.

The International Congress of Medicine in 1890 was held in Berlin, and the American pharmacologist, Horatio Wood, read a paper stressing, with statistical data, the relatively far greater safety of ether as compared with chloroform. The

Germans were impressed, and the surgeon, Ernst Gurlt, was commissioned independently to compile statistics relating to deaths under the two agents. Gurlt's figures, also, showed the superior safety of ether.

By 1894 many German surgeons were giving ether a re-trial—using either Julliard's mask or Wanscher's inhaler, and in the following year a few French surgeons (apart from those at Lyons) followed suit. But by the close of the century continental interest in etherization had begun to wane. For this, two main reasons can be found. One was the widely held belief that ether gave rise to post-operative chest complications; the other was the steadily growing interest in non-inhalation anæsthesia.

The adoption of anæsthesia in 1846 had made surgery more bearable for the patient, but his chances of survival were scarcely improved, because the occurrence of those septic conditions, known collectively as hospitalism, was increasing. However, after Lister's antiseptic method had been applied during and after the Franco-Prussian War, and when during the eighteen-eighties, the Germans replaced it by asepsis through heat sterilization, then at last visceral surgery could be and actually was undertaken with confidence, both in Germany and, through the German example, in the United States of America. In both countries the lack of expert anæsthetists was immediately felt. The surgeons looked with envy at the English specialist anæsthetist, but the urgency of the problem led them, during the eighteen-nineties, to find their own solution. They themselves prepared a painless operating field, at first by Schleich's local infiltration, later by regional nerve blocking and by spinal analgesia.

In Great Britain these new methods were looked at askance, although at the time of the jubilee of ether anæsthesia in 1896, and of chloroform in the following year, English anæsthetic practice itself had come under the critical scrutiny of men such as Hewitt and D. W. Buxton. Reluctantly they reached the conclusion that, compared with the enormous initial advances of 1846-7, subsequent progress had been in some ways disappointing. In particular they deplored the fact that the ordinary medical student—the potential occasional anæsthetist—still did not receive any adequate teaching in anæsthetics. The specialist anæsthetist, on the other hand, might well congratulate himself on his mastery of the techniques of nitrous oxide, of ether, and of chloroform anæsthesia—to which last agent the Hyderabad Chloroform Commissions of 1888 and 1889 had redirected attention—and there could be no doubt that in the field of inhalation anæsthesia he still excelled.

The Measurement of Personality. [*Résumé*]

By H. J. Eysenck, Ph.D.London
Psychological Laboratory, The Maudsley Hospital

Both terms in the title of this paper, "measurement" and "personality" need, definition and discussion, as common usage of these words is rather indeterminate. Personality we shall define, following Warren (1934), as "the integrated organization of all the cognitive, affective, conative, and physical characteristics of the individual as it manifests itself in focal distinctness to others." This rather inclusive definition distinguishes "personality" from such more narrowly circumscribed terms as "temperament" and "character," which refer more specifically to the affective and conative organization of the individual respectively, from "intelligence," which refers to the cognitive aspects, and from "constitution," which refers to the physical aspects.

If we accept this definition, it becomes clear at once that we cannot in any intelligible fashion talk about the *measurement* of personality. Without going into a detailed discussion of the principles of measurement (Campbell, 1928, 1938; Scates, 1937; Thomas, 1942; Young and Householder, 1941; Gulliksen, 1946), it is apparent that measurement can only proceed along one dimension at a time; we can measure the height of a building, or its length, or its depth—we cannot measure all three at the same time.

This difficulty lies at the back of Henderson and Gillespie's (1943) statement that "if it is doubtful what we measure with 'intelligence' tests, it is still more uncertain what we would try to measure if we tackled 'emotions' in a similar way". In other words, while in the cognitive sphere we have succeeded to some extent in isolating one "dimension" of personality for measurement, there is still no agreement about the "dimensions" existing in the orectic sphere, and consequently the very basis for any kind of measurement is absent.

Under those conditions, it behoves us to study the methods used in establishing the cognitive dimension, and to inquire whether the same methods might not with advantage be applied to the orectic sphere as well. Two main contributions may be discerned in the development of the science of intelligence measurement: one, the creation of a large number of objective, reliable tests validated against external criteria, such as judgments by teachers, parents, officers, psychiatrists, and so forth; and second, the elaboration of statistical methods, more particularly the method of factor analysis (Burt, 1940; Thomson, 1939; Guilford, 1937; Thurstone, 1935; Spearman, 1927), which ensure unidimensionality and internal validity to these tests.

In noting these two contributions, we find that both claim "validity" of testing as part of their achievement. This indicates that there are two different types of "validity". Validity is usually defined as a measure of the extent to which a test agrees with a criterion; e.g. the extent to which an intelligence test succeeds in measuring intelligence. But the example itself shows immediately that this definition is almost valueless; how *can* we know how well a test measures a quality, such as intelligence, unless we already have a perfect measure of that quality? True, we have a number of obviously imperfect measures of intelligence, such as teachers' ratings, success in school and college, or earning capacity, but as these criteria themselves are unequal, the question arises, which are we to choose? What criterion shall we use for choosing our criterion? In this way we become involved in an infinite regression, and our definition, so simple and obvious at first glance, is seen to be swallowed up by a metaphysical hydra.

As opposed to this "external" type of validity, psychologists have elaborated an "internal" validity, derived from the pattern of interrelations obtaining among groups of tests. Thus, fifty tests presumed to measure a great variety of aspects of intellectual ability are given to large numbers of subjects, the intercorrelations of the tests are calculated, and from the pattern or matrix of their intercorrelations certain "factors" are extracted whose validity does not depend on any outside criterion, but is derived from the whole "gestalt" of the original matrix. In this way, Spearman originally proved that there is one general factor, "g", which is common to all cognitive tests, in various proportions; in this way, we have learned since that there are a number of more specialized groups of abilities, common to some but not all tests, called verbal, arithmetical, visuo-spatial, æsthetic, mechanical and perceptual ability.

Superficially, the fact that we have two kinds of validity seems to face us with an impasse. The "intelligence" measured by the common-sense type of person who relies on external validity is not acceptable to the statistically minded psychologist, who is apt to raise awkward questions about the external criterion and its validity; the "g" measured by the statistical psychologist is said (by the non-statistician) to be a mere statistical artefact, without any real psychological meaning. Fortunately, there is a strong tendency for both types of validation to give the same answer to the question—which is the best test of intelligence? When we compare the correlations of a number of tests with an external criterion, we see that some tests correlate highly, others show low correlations. When we intercorrelate these same tests, and factor-analyse the resulting matrix, we find that some tests have high correlations with the resulting "g" factor, while others have low correlations. Now in such a situation it is usually found that the test that correlates highly with the outside criterion will also be the test that has a high factor saturation, and the test that shows a low correlation with the outside criterion also has a low factor saturation. In that way, we can identify our statistical factor, "g", with the psychological dimension, intelligence, and justly claim that we have succeeded in identifying and measuring this particular aspect of personality.

These considerations suggested that a similar process in the orectic field might lead to similar results; in other words, it appeared that the use of factorial analysis in connexion with temperament, character, and constitution might lead to the isolation, and finally to the measurement, of the main dimensions in those fields. Working on that basis, a team of psychologists and psychiatrists spent some four years at Mill Hill Emergency Hospital, and at the Maudsley Hospital, carrying out large-scale factorial and experimental studies into those problems; preliminary results have been published in a series of papers (*see* References: Eysenck, with Furneaux, Halstead. Himmelweit, Rees, and Yap). More recently, a complete account of this work has been published in book form (Eysenck, 1946). Only the main conclusions can be presented here.

Using factorial techniques as "internal validity" criteria, and psychiatric judgments, personal history data. Service career, and similar data as "external validity" criteria, we found that just as there is one general factor dominant in the cognitive field, so there are discernible strong general factors in the fields of character.and temperament as well, using our definitions of these terms as presented in the first paragraph of this paper.

In the field of character, or "conation", there appeared a very powerful factor which might be called neuroticism, maladjustment, neurotic constitution, lack of integration, or lack of will-power; this factor clearly distinguished (1) the person referred to a neuropsychiatric hospital from the person not so referred; (2) the neurotic patient judged by the psychiatrist to be severely ill from the patient judged to be less severely ill; (3) the "normal" person outside the hospital whose adjustment to Army, factory, or life was considered faulty from the person whose adjustment was more successful.

These findings were checked and counterchecked using a great variety of objective, reliable tests. The most successful of these tests was the "body sway" test of primary suggestibility, which was described in a paper read to this Society two years ago (Eysenck, 1943*a*). Another successful test was an objective version of the Rorschach ink-blot test, in which the subject has to select responses from a printed list, instead of providing original responses. A third type of test which gave adequate differentiation was a test of persistence, requiring the subject to maintain a certain posture involving fatigue of various muscles for as long as possible. Questionnaires, although less objective than the other tests in our battery, tended to give excellent results when given to suitable groups.

Other differences between persons situated towards the "neurotic" end of the dimension under discussion, and persons situated towards the "normal" end included the following: neurotics tended to be slightly less intelligent, although the difference was too small to be of any practical importance; they tended to have a markedly more leptomorphic body-build; they tended to score very badly on tests of dark-vision; they had a slow "personal tempo", low fluency, extreme perseveration (as opposed to lack in persistence) poor effort response, and a very uneven and irregular work-curve. On all these points, as well as on many others, there was good correspondence between external and internal criteria.

Whenever attempts were made to investigate the distribution of this factor, we found a roughly normal curve of distribution; this would appear to indicate that this factor may have a constitutional basis, and may be subject to multifactorial inheritance, like intelligence. Investigation of this possibility is urgently needed before any definite claims can be made as to the genotypical reality of our findings; factor analysis cannot give any but descriptive, phenotypical results, the possible causation of which must be investigated by other methods more directly concerned with the specific problem under discussion.

It is possible that the use of the term "neuroticism" in denoting this factor may be open to criticism, and indeed the multiplicity of meanings associated with

Under those conditions, it behoves us to study the methods used in establishing the cognitive dimension, and to inquire whether the same methods might not with advantage be applied to the orectic sphere as well. Two main contributions may be discerned in the development of the science of intelligence measurement: one, the creation of a large number of objective, reliable tests validated against external criteria, such as judgments by teachers, parents, officers, psychiatrists, and so forth; and second, the elaboration of statistical methods, more particularly the method of factor analysis (Burt, 1940; Thomson, 1939; Guilford, 1937; Thurstone, 1935; Spearman, 1927), which ensure unidimensionality and internal validity to these tests.

In noting these two contributions, we find that both claim "validity" of testing as part of their achievement. This indicates that there are two different types of "validity". Validity is usually defined as a measure of the extent to which a test agrees with a criterion; e.g. the extent to which an intelligence test succeeds in measuring intelligence. But the example itself shows immediately that this definition is almost valueless; how *can* we know how well a test measures a quality, such as intelligence, unless we already have a perfect measure of that quality? True, we have a number of obviously imperfect measures of intelligence, such as teachers' ratings, success in school and college, or earning capacity, but as these criteria themselves are unequal, the question arises, which are we to choose? What criterion shall we use for choosing our criterion? In this way we become involved in an infinite regression, and our definition, so simple and obvious at first glance, is seen to be swallowed up by a metaphysical hydra.

As opposed to this "external" type of validity, psychologists have elaborated an "internal" validity, derived from the pattern of interrelations obtaining among groups of tests. Thus, fifty tests presumed to measure a great variety of aspects of intellectual ability are given to large numbers of subjects, the intercorrelations of the tests are calculated, and from the pattern or matrix of their intercorrelations certain "factors" are extracted whose validity does not depend on any outside criterion, but is derived from the whole "gestalt" of the original matrix. Fortunately, there is a strong tendency for both types of validation to give the same answer to the question—which is the best test of intelligence? When we compare the correlations of a number of tests with an external criterion, we see that some tests correlate highly, others show low correlations. When we intercorrelate these same tests, and factor-analyse the resulting matrix, we find that some tests have high correlations with the resulting "g" factor, while others have low correlations. Now in such a situation it is usually found that the test that correlates highly with the outside criterion will also be the test that has a high factor saturation, and the test that shows a low correlation with the outside criterion also has a low factor saturation. In that way, we can identify our statistical factor, "g", with the psychological dimension, intelligence, and justly claim that we have succeeded in identifying and measuring this particular aspect of personality.

These considerations suggested that a similar process in the orectic field might lead to similar results; in other words, it appeared that the use of factorial analysis thymes, while our extraverts (hysterics) tended to be eurymorphic in body-build. But in Kretschmer's system, hysteria tends to go with the schizothyme type, and depression with the cyclothyme type; consequently it does not appear that any identification of these two systems is possible. On colour-form tests, on which great differences usually become apparent between cyclothymes and schizothymes—the former being more colour-reactive, the latter more form-reactive—and on the reversal-of-perspective tests, in which also great differences usually appear—the cyclothymes giving fewer reversals than the schizothymes—no differences appeared between our extravert and introvert samples.

Our findings, while largely based on various neurotic groups, are also applicable, in our view, to normal groups; whenever we have had an opportunity of testing normal samples of the population we have found precisely the same differentiation in our test results as we found in our neurotic groups. As the total number of cases studied is quite considerable, approaching twenty thousand, we believe that our conclusions, while no doubt subject to many detailed criticisms and improvements, are perhaps a useful first approximation to the goal we set ourselves, viz. the isolation and measurement of the major dimensions of personality. This hope is strengthened by the fact that whenever it was found possible to check certain partial findings against the results obtained by other workers in the field, using quite different types of subjects (students, children, factory workers, &c.), considerable agreement was evident. Similarly, our main conclusions on the factorial side are not in contradiction to the results obtained in certain pioneer studies by Burt, Webb and others. A full discussion of the relation of our work to that of others will be found in "Dimensions of Personality" (Eysenck, 1947).

The picture of personality which emerges from these studies bears some similarity to a globe, or sphere. Any point on that sphere can be identified by reference to three axes constructed at right angles to each other, and penetrating the sphere. One of these axes is the familiar cognitive axis, labelled "g" or intelligence; the second axis is labelled "neuroticism", and may be identified with the conative side of personality; the third axis is labelled "introversion-extraversion", and corresponds to the affective side of personality. In actual fact, these three axes are not quite orthogonal, but show a slight degree of obliqueness; in other words, the angles separating them are not right angles, but only approach this particular structure. For instance, intelligence and neuroticism show a negative correlation of –0·30, corresponding to an angle deviating by 3 degrees from a right angle. A similar correlation is found between introversion and intelligence, again slightly tilting the two axes towards each other. But by and large these departures from orthogonality are too small to influence the general picture to any significant extent, and for practical purposes we may assume independence among our dimensions.

If we want to extend our personality sphere still further, so as to take in the physical aspect as well, we must add a fourth axis, at right angles to the other three; this addition of course necessitates a four-dimensional representation, and makes it impossible to visualize the resulting structure. Again slight departures from orthogonality must be admitted; leptomorph body-build correlating to the extent of 0·30 approximately with "neuroticism", and to the same extent with "introversion". It is not possible to say whether such a four-dimensional picture is adequate, or whether other dimensions will be required; only further research can answer this question.

The main usefulness of these studies, assuming that our general conclusions be accepted, will probably lie in two fields. In the first place, practical work in industrial psychology, vocational guidance, occupational selection, in clinical psychology, and in educational psychology, may benefit from the possibility of carrying out objective psychiatric terms such as ''neurosis'' makes them of doubtful value if applied to more specific findings with operational connotations. However, no other term could be found to obviate these difficulties, and in any case problems of nomenclature are of semantic rather than of scientific interest.

In the field of temperament, or ''affection'', there appeared a factor which seemed to be very similar in nature to Jung's extravert-introvert dichotomy. Among the neurotic patients investigated, this distinction pointed to a dimension ranging from one extreme, containing the more hysterical types of symptoms and reactions, to the other extreme, containing anxiety, depression, obsessional and other ''dysthymic'' reactions. These two groups of symptoms, the hysteric and the ''psychasthenic'' or, as we prefer to call it, the affective or dysthymic, are of course the prototypes of Jung's famous dichotomy, and thus our results strongly support his claims. It should be noted, however, that we regard extraversion and introversion not as types in the sense that a given person is either an extravert or an introvert; we merely regard these two concepts as the extreme ends of a normal curve of distribution, with the majority of people falling somewhere in between the extremes. Support for this view of a normal distribution of this factor comes from actually plotted distributions, all of which resemble the normal curve so familiar from work on intelligence tests.

Experimental measurement along this dimension is based on a variety of findings, involving a number of tests from various modalities. To begin with, there is strong evidence that the introverts tend to be leptomorphic in body-build, while the extraverts tend to be eurymorphic. Jones and Richter have shown that effort response is poorer in the introverts, and choline esterase secretion more pronounced. Intellectually, the introverts tend to score more highly; when equated for intelligence, introverts tend to give markedly higher scores on vocabulary tests than do extraverts. Introverts tend to carry out various tasks slowly, but accurately; extraverts tend to do them quickly and inaccurately. Introverts tend to have a high level of aspiration, to be very rigid in their demands of themselves, and to underrate their own performances; extraverts tend to have very low levels of aspiration, to lack the rigidity of the introvert, and overrate their own performances. These tendencies are exaggerated in the neurotic extravert (i.e. the hysteric) and in the neurotic introvert (i.e. the dysthymic); normal subjects are intermediate between these extremes.

Extraverts also tend to be differentiated from introverts by their æsthetic preferences, in terms of their sense of humour (both with respect to how amusing they find various types of material, and which type of material they find most amusing; on the whole, introverts find all types of material less amusing than do extraverts, but in the field of sexual humour in particular this difference is much more pronounced than elsewhere), and in terms of their æsthetic creativity, as shown for instance in the Lowenfeld Mosaic Test, where introverts tend to make compact, extraverts scattered designs. Questionnaires also show marked differences between introverts and extraverts, as do various other tests not enumerated.

It is important to clarify the relation of our introvert-extravert factor to Kretschmer's cyclothyme-schizothyme typology. It is our considered opinion, based upon a variety of experimental evidence, that these two typologies cannot justifiably be considered identical, and that in reality there is no relation between them whatsoever. In terms of experimental work, this conclusion follows from our demonstration that tests which had been shown by others to differentiate between cyclothymes and schizothymes did not discriminate at all between extraverts and introverts. The tests used included a variety of colour-form tests, reversal-of-perspective tests, and measurements of body-build. As already explained, we found that introverts (dysthymics, i.e. persons suffering from anxiety and reactive depression) tended to be leptomorphic in body-build, which would align them with Kretschmer's schizo-

Section of Neurology

President—DOUGLAS MCALPINE, M.D., F.R.C.P.

[*November* 7, 1946]

MEETING AT THE MAIDA VALE HOSPITAL FOR NERVOUS DISEASES, W.9.

Ataxic Nystagmus in Disseminated Sclerosis.—WILFRED HARRIS, M.D., F.R.C.P.

A man aged 39, began to be tremulous and unsteady three years ago, with weakness especially of the left arm and leg. He is now a typical case of disseminated sclerosis, is so unsteady that he cannot walk alone without a stick and someone to assist him. Typical inco-ordination of the arms, and some bladder weakness. Deep reflexes much increased. He shows two forms of nystagmus:

(1) Jelly nystagmus, a quivering motion of the eyeballs, which can only be seen by direct ophthalmoscopy, and

(2) Ataxic nystagmus. This latter form I described in *Brit. J. Ophthal.*, 1944, 28, 40. Briefly it consists of nystagmus of the outer eye only, the inner eye not quite reaching the canthus in conjugate lateral movement. This peculiar one-sided nystagmus of the outer eye may be seen both on looking to right and to left, or it may be to one side only. In this patient it is more marked on looking to the right, the right eye then showing coarse nystagmus with quick outward movement and slow return, the left eye remaining stationary and not quite reaching the inner canthus. I have seen a large number of similar cases in the last twenty years since I first noticed this type, and I consider it to be pathognomonic of disseminated sclerosis, as it does not occur in any other condition. It is obviously associated with weakness of the lateral conjugate movement of the eyes.

Jelly nystagmus was considered by Kinnier Wilson, 1940, "Neurology", 1, 161, London, quoting Paton, to be pathognomonic of disseminated sclerosis, but this form has been met with in other conditions.

Dr. Harris then showed a film produced by the Gaumont-British Co. of the patient walking; it also illustrated the inco-ordination of the arms. A close-up showed well the ataxic nystagmus.

The President said that the film was most interesting. It was probable that they had all seen this type of nystagmus, but had not realized its significance in relation to disseminated sclerosis.

Tuberose Sclerosis with Intracranial Calcification and Lesions of Bone.—HELEN DIMSDALE, M.R.C.P.

L. S., female, aged 39.

Family history.—8 normal siblings. Father dead—"consumption" and alcoholism. Mother aged 83, alive and well. No family history of fits or mental deficiency.

History.—Development normal till age of 5 when she started to have fits and a rash was noticed on her face. Dull at school, but learned to read and write. Earned her living as a domestic worker. Incidence of fits variable and unaffected by sedatives.

On examination.—Facial adenoma sebaceum of Pringle type, scattered cutaneous and subcutaneous fibromata, large shagreen patch in lumbosacral region. Adherent lobes to ears. C.N.S.: High-grade mental defective. Fundi: no lesions detected. No focal signs.

Investigations.—C.S.F.: Normal pressure and constituents. Blood W.R. negative. Serum calcium: 10·3 mg.%. Inorganic phosphorus: 3·4 mg.%. Serum phosphatase: 3·0 units. X-rays: Chest: N.A.D. Skull: Hyperostosis frontalis interna. Choroid plexuses heavily calcified. Two patches of paraventricular calcification. Hands and feet: Periosteal thickening metacarpals and metatarsals, areas of rarefaction in terminal phalanges suggestive of small cysts. Spine: vestigial twelfth ribs; no evidence of spina bifida.

measurement along the two dimensions indicated. In the second place, the provision of batteries of tests for such measurement will make possible a concentrated attack on such theoretical problems of outstanding importance as the influence of nature and nurture in the genesis of conative and affective traits, or the relation of personality variables to a great variety of psychological phenomena. Only by such further experimentation can the claims made here be proved or refuted, and our knowledge in the field of personality measurement be extended beyond the present narrow boundaries which have prevented its growth for too long.

is sufficient to remove an inch or so of the styloid process and there is no need to do anything more to the nerve.

I agree with Dr. McAlpine that the type of case which appears to be suitable for this operation is one in which there is no evidence of any primary condition which is apparently causing the neuralgia and a trigger area should be present in the tonsillar region; if these two conditions apply the operation should prove a very successful one.

Dr. Wilfred Harris: Glossopharyngeal neuralgia is rare compared to trigeminal tic, perhaps in the ratio of 1 : 500. A characteristic sign sometimes met with is a hawking cough in the effort to arrest the pain. Avulsion of the nerve after dissection behind the angle of the jaw has proved very satisfactory in many cases, though it may prove a difficult operation. It has the advantage that steady traction may bring away with it both the jugular and petrous ganglia. Mr. Wilson's method may prove easier to those accustomed to work inside the mouth.

Dr. C. Worster-Drought said that he thought the very satisfactory result of the operative treatment in this case depended on the situation of the "trigger zone". In other cases of glossopharyngeal neuralgia and without such a "trigger zone" the result might not be so successful. In the cases he had seen, complete avulsion of the nerve through an incision in the upper part of the neck had usually resulted in complete relief. The portion of the nerve removed, however, must include both the ganglia, viz. the jugular ganglion and the petrous ganglion. In one case in which the ninth nerve was divided between the two ganglia the pain was not relieved.

Mr. G. C. Knight: I would like to congratulate Mr. Wilson upon devising such an excellent and simple method of treatment of glossopharyngeal neuralgia. There can be no doubt that the operation formerly employed of deep dissection of the neck to secure a division of the glossopharyngeal nerve at the base of the skull could be a most difficult procedure in a thick-necked individual, for the glossopharyngeal nerve is extremely small in size, being no more than two to three strands of cotton in thickness, and to find so small a nerve at a great depth following retraction of the carotid and jugular vessels and to identify it running down upon the posterior border of the stylopharyngeus is sometimes a matter of difficulty.

The only advantage that could be claimed for the high operation was that it was possible to avulse the ganglion on the nerve from the base of the skull, and that degenerative changes in this ganglion would sometimes be demonstrated at section.

Mr. Dickson Wright thought that Mr. Wilson's operation was very ingenious and simplified the approach to the nerve. If avulsion of the nerve was done in the neck operation and the two ganglia of the nerve were secured in this way a gush of cerebrospinal fluid usually followed. This avulsion prevented any possible recurrence of the malady and was worth doing and the leakage of cerebrospinal fluid caused no anxiety because the wound was tightly sutured.

Compression Neuritis of Both Median Nerves in the Carpal Tunnel: Surgical Decompression. Klippel-Feil Deformity of Neck. Sprengel Shoulder.—W. Russell Brain, D.M., and A. Dickson Wright, M.S.

E. W., married woman, aged 57. Two years' history of pain in front of right wrist spreading to thumb, index and middle fingers, like electricity, and associated with numbness in thumb, wasting of outer aspect of thenar eminence and weakness of thumb. Four weeks: Pain and paræsthesiæ in left thumb, index and middle fingers. Left shoulder always higher than right. Occasional pain in neck on extension.

Severe wasting and weakness of abductor brevis and opponens pollicis of right hand, and slight of left. Weakness of extension of right thumb at metacarpophalangeal and interphalangeal joints. Slight impairment of appreciation of light touch and pin-prick over distal half of palmar surfaces of thumb, index and middle fingers and radial half of ring finger of both hands and corresponding dorsal surfaces of terminal phalanges: no loss of tactile discrimination or postural sense. Sensory loss greater on right hand than left.

Electrical reactions.—Faradic response lost in right abductor brevis and opponens pollicis, and sluggish in abductor longus and the extensors of the thumb on both sides.

Neck very short; extension somewhat limited, some pain on lateral flexion. Prominence of lower cervical spinous processes. Left scapula higher than right.

X-rays (Dr. James Bull).—Fusion of cervical vertebræ except C3-C4 and C5-C6. Bilateral cervical ribs present. Left scapula is abnormally high and its vertebral border is angulated towards the spinal column in a "V" shape. At this point an

Comment.—The intracranial calcification is probably produced by calcareous degeneration in subependymal sclerotic nodules. The nature of the bony changes in tuberose sclerosis is obscure. Gottlieb and Lavine (1935) suggested that the lesions might be neurotrophic. Hall (1940) described bony lesions of two types, due to neurofibromatosis and rheostosis. Evidently tuberose sclerosis may occur in association with a generalized tissue dysplasia.

Glossopharyngeal Neuralgia treated by Trans-Tonsillar Section of the Nerve.—C. P. WILSON, C.V.O., F.R.C.S., and D. MCALPINE, M.D., F.R.C.P.

M. J., female aged 47. In June 1945 suddenly experienced a severe pain in the right ear when eating an apple. The pain lasted a few seconds. In August, during a meal, pain like "red hot needles" was felt at the back of the tongue on the right side. In subsequent attacks the pain shot up from the back of the tongue to the right ear. The pain was brought on by swallowing solids, liquids or even saliva. The frequency of the attacks gradually increased and by April 1946 they were recurring several times a day and even at night causing loss of weight and sleep.

14.5.46: Admitted Neurological Ward, Middlesex Hospital. Healthy woman with no abnormality in her nervous system apart from the right glossopharyngeal nerve. The attacks of pain during eating were confirmed. A trigger zone existed on the tonsil and adjacent surface of the tongue. The attacks of pain lasted about fifteen to thirty seconds. Cocainization of the trigger zone before meals almost completely abolished the pain.

5.6.46: Right tonsil removed by dissection and glossopharyngeal nerve exposed deep to tonsillar fossa. The nerve was divided and ⅜ in. was removed.

The patient has been completely free from pain since the operation and has gained over a stone in weight. There is loss of taste over the posterior third of the tongue on the right side and hypæsthesia over the distribution of the right ninth nerve.

Dr. D. McAlpine: This case shows characteristic features of glossopharyngeal neuralgia, the recognition of which we owe to Harris (1921), namely paroxysmal pain referred to the back of the tongue and the tonsil area, radiating to the ear, and in addition the existence of a trigger zone. The radiation of the pain is explained by the existence of the nerve of Jacobson which runs from the petrous ganglion to the tympanic plexus and thus to the tympanic membrane, middle ear and mastoid cells. The glossopharyngeal nerve does not supply the external auditory canal or the pinna, and in order to explain the occurrence of pain in these areas it is necessary to postulate an overflow along the auricular branch of the vagus which also takes origin from the petrous ganglion, or by the auriculotemporal branch of the trigeminal nerve which connects with the otic ganglion and thus indirectly with the glossopharyngeal nerve through the small superficial petrosal nerve.

The diagnosis of glossopharyngeal neuralgia is straightforward provided the situation and radiation of the pain and its relationship to swallowing is remembered. The diagnosis can be substantiated by cocainization of the tonsil area and back of the tongue, a procedure which relieves the pain.

Up to the present time operative treatment in severe cases has been limited to either (1) an intracranial resection of the ninth nerve using the suboccipital route, or (2) avulsion of the nerve high in the neck. Both of these operations are not devoid of risk. No previous report of a trans-tonsillar section of the nerve can be traced. The operation is a simple one in the hands of an experienced ear, nose and throat surgeon. In the present case the patient has been entirely free from pain for five months and there seems no reason why the result should not be permanent. In cases in which a trigger zone exists in the ear and not in the throat, it is probable that an intracranial operation may be necessary, but from our experience with the present case it would appear that if a trigger zone exists in the tonsil area then trans-tonsillar section of the nerve should be carried out. Only if such a measure fails to cure the pain should the intracranial approach be considered.

Mr. C. P. Wilson said that from the purely operative point of view the surgical procedure is quite simple. The tonsil is removed and the muscular layer in the tonsillar bed consisting of mixed fibres of the superior constrictor of the pharynx and palato-pharyngeus is divided. The nerve is found quite easily just outside the muscle layer in the lower part of the fossa as it passes forward to supply the posterior third of the tongue. It can quite easily be divided in this situation and as much of the nerve trunk can be removed as is felt necessary. There should be no very great difficulty in removing the nerve up as far as the base of the skull.

The type of case that I have previously dealt with is that in which the glossopharyngeal neuralgia is associated with an elongated styloid process pressing into the tonsillar bed and in these cases it deteriorate and the left eye to improve a little. Right vision disappeared completely by mid-June. At the same time the left leg became weak.

First seen in July 1946. She looked ill and had obviously lost weight. Temperature then running intermittently between 99°-101° F. There was extreme tenderness over the whole of the left scalp and also over the left temporo-mandibular joint so that she was unable to open her mouth properly. There was a superficial eruption over the left scalp. Both superficial temporal arteries were palpable but not pulsating.

V.A.—R. no P.L. L. J.6 corrected. Bilateral primary optic atrophy, the hazy margins of the discs being due to vitreous haze. Arteries markedly narrowed. Right pupil does not react directly to light. Left pupil does not react consensually. No gross field defect of left eye. Minor left spastic weakness with increased deep reflexes, ankle clonus, and an extensor-plantar response. No sensory defect.

Investigations.—Blood-count: R.B.C. 3,300,000; Hb. 60%: W.B.C. 5,000 with normal differential. E.S.R. (Wintrobe corrected) 22 mm. in one hour. W.R. negative in blood and C.S.F.

C.S.F.: Pressure 110 mm. Cells 3 lymphos. Protein 20 mg. Lange negative. X-ray of skull normal. Fractional test meal normal. Section of temporal artery shows recanalization of the previously thrombosed vessel lumen, with chronic inflammatory infiltration and occasional giant cells in the wall.

Progress.—There has been slow but steady improvement in the general condition with loss of tenderness of the scalp. There has, however, been no change in the physical signs. Temperature settled by the end of August, but the sedimentation rate was still 29 mm. at the beginning of September (*see* Cooke *et al.* 1946, Jennings 1938, Horton and Magath 1937).

Professor P. C. Cloake congratulated Dr. Kremer on his presentation of a case, which demonstrated most of the characteristic features of the disease. Many such cases must have gone unrecognized in the past.

He thought the pain in the back of the neck and left side of the head might have been due to involvement of the left occipital artery in the same process. Very frequently, as in this case, the ophthalmic arteries were affected, leading to optic atrophy and, in two of his own cases, definite signs of focal cerebral lesions were present, as well as mental changes, pointing to more diffuse disease.

He and his co-workers had drawn attention to the evidence of widespread affection of arteries in other parts of the body, giving rise to pain in muscles and joints and degeneration of peripheral nerves months or years before the appearance of temporal arteritis enabled the nature of the disease to be recognized.

The pathological change in the vessel wall was a focal necrosis of the media, with inflammatory reaction spreading from the adventitia to the media and tending to extend longitudinally. Giant-cell formation was present in foci of granulation tissue in the media, following upon the necrosis. Intimal thickening occurred and led on to thrombosis of smaller arteries. Veins were rarely affected.

The President stated that this was the first case of temporal arteritis that had been shown before this Section, but on account of its neurological interest it was probable that others would be shown in the future. As Professor Cloake had already pointed out, the process is more widespread than the name would suggest; in the case just shown the middle cerebral artery was involved. Published accounts of the disease had, on the whole, indicated a favourable prognosis, but in view of the nature of the arterial changes and their occurrence in elderly patients, it seemed that they would be subject to vascular accidents at a later date. In the cases reported by Cooke, Cloake and others, three of the patients died within two years of the onset of the disease, while only one patient made a good recovery.

Paget's Disease of the Skull with Platybasia.—JAMES BULL, M.B., M.R.C.P.

Housewife, aged 64, had noticed her head increasing in size for ten years. For seven or eight years she had become increasingly deaf, the right ear being more severely affected than the left. For one or two years she had had head noises and for over a year the right side of the face had been twitching. She complained of her head feeling heavy, and occasional unsteadiness in walking. The family history was not relevant.

On examination.—Head circumference 25¼ in. The frontal and temporal regions bulged particularly. Optic discs were normal, marked right-sided facial hemispasm abnormal bone articulates with the spinous process of C5 and with the vertebral border of the scapula.

Operation (October 14, 1946, by Mr. Dickson Wright).—The right median nerve was swollen for about half an inch above the carpal ligament and under the ligament. The carpal ligament was incised. The left median nerve was then exposed. This was also swollen but was pinker than the right. The left nerve divided into two parts about one inch above the upper end of the ligament both parts running together under the ligament. The ligament was incised and the wound sutured.

Dr. Russell Brain said that the syndrome of partial thenar atrophy was first described by Ramsay Hunt (1909, 1911, 1914) and subsequently by various observers, who had usually laid stress upon the absence of sensory disturbances. There was no evidence that it was due, as Hunt had suggested, to compression of the thenar branch of the median nerve where it turned back over the distal end of the transverse carpal ligament. Zachary (1945) had shown that a predominantly motor symptomatology could occur when the whole median nerve was compressed, as in these cases, in the carpal tunnel. The main diagnosis was from the costoclavicular syndrome, in which, though partial thenar atrophy might occur, sensory disturbances over the thumb and index finger were extremely rare.

Mr. A. Dickson Wright: The operation was done at the suggestion of Dr. Russell Brain who, in elucidating this syndrome, has clarified still one more form of "Neuritis". By discovering a mechanical cause for attrition of the median nerve he has made a most valuable contribution to neurology. The nerve was found to have responded to pressure and friction in the same useless way as elsewhere, viz. by swelling so that pressure and friction were increased and a vicious circle established which had to be broken by the operation of dividing the anterior carpal ligament from end to end so as to free the attrition. Similar situations were met with in disc lesions, cervical ribs and chafing of the ulnar nerve at the elbow. It was noticed at operation that the nerve was thickened for about two inches above the carpal ligament and there were characteristic pinkish and purplish colour changes in the nerve with marked increase in the fascicular markings. The extent of the swelling below the tunnel was not observed as it was not thought necessary to open up the palm but from experience it would be expected to find the swelling extending into the various branches of the nerve. Trouble in the form of prolapse of the flexor tendons seemed not to occur, presumably because the wrist is always in extension during gripping.

Dr. C. Worster-Drought said that he remembered rather an elaborate paper on the subject of "Partial Thenar Atrophy" by Wartenberg (1939) published shortly before the War. Wartenberg considered that the condition was more likely to occur when the branches of the median nerve supplying the outer part of the thenar eminence were abnormally situated. Wartenberg himself did not consider the condition due to a compression neuritis but apparently to general toxic factors acting on a group of muscles (opponens and abductor pollicis) that were phylogenetically of recent origin.

Most of the cases he (Dr. Worster-Drought) had seen did not show any sensory impairment over the area of median nerve supply but they might complain of localized paræsthesia. He considered that Dr. Russell Brain and Mr. Dickson Wright were to be congratulated on introducing a treatment for the condition. He assumed that the operative treatment they described would be more applicable to those cases showing definite sensory impairment or loss.

The President congratulated Dr. Brain on his presentation of this difficult case, and for bringing to their notice a new pathological explanation for certain cases of wasting of the thenar muscles. Dr. Brain had pointed out that the distribution of the wasting was similar to that found in certain types of cervical rib. The differential diagnosis would seem to lie in the distribution of the sensory loss and in the absence of vascular changes which were not unusual in cases of cervical rib.

Temporal Arteritis.—Michael Kremer, M.D., F.R.C.P.

Mrs. L. P., aged 75. In 1941 she developed malaise, night sweats, loss of weight, loss of appetite, and cough with some sputum. She was regarded as a tuberculosis suspect and kept under observation by the tuberculosis officer. X-ray of chest and sputum examination were negative, and she recovered completely in six months.

August 1945: Fell on the back of her head and since then has had tenderness of the occiput. No amnesia or other signs of intracranial damage. *March 1946:* Developed a severe pain spreading up the back of her neck and over the left side of the head. The scalp became extremely tender so that she was unable to sleep on the left side. Her general condition deteriorated and she began to run a temperature up to 101° F. June 1946: Vision deteriorated in the left eye, taking two to three days to diminish to light perception only. Ten days later the right vision began to such as that shown here, is quite obvious without resource to refined radiological methods of diagnosis. Platybasia in Paget's disease seldom causes symptoms of nerve or hind-brain pressure. This is true of the four cases observed by the author, and Moreton (1943) described six such cases in a series of 98 acquired platybasias. None of his six cases had signs of pressure from the basilar invagination. Ray (1942), on the other hand, described one case in a woman of 47 with an unsteady gait, a weak right arm and a dragging leg for a year. Suboccipital and upper cervical decompression improved her condition. Ray went so far as to say that it was likely that basilar deformity occurs in some degree in the majority of people with advanced Paget's disease.

The author demonstrated radiographs and diagrams illustrating the angle formed by the plane of the hard palate and that of the atlas. The difficulty of measuring the basilar angle of the skull was pointed out, in that the anterior end of the foramen magnum, an essential landmark in measuring the angle, is not visible in lateral radiographs owing to the superimposition of the mastoid processes. Furthermore (Lindgren, 1941) it is the occipital condyles, situated paramedially, and not the clivus, which first give way, and thus the basilar angle would not be altered in early basilar impression. Finally the empirical line drawn by Chamberlain (1939) from the back of the foramen magnum to the hard palate was stated by him to lie above the tip of the odontoid process of the axis. Saunders (1943), however, showed that 35 out of 100 normal cases which he examined had odontoid processes projecting above Chamberlain's line.

Professor P. C. Cloake said that he had not had an opportunity of testing Dr. Bull's method of diagnosing platybasia by measuring the angle referred to. He agreed that there was great difficulty in practice in measuring the so-called basal angle. He thought that in acquired cases the atlas did not always tilt forwards and upwards, as suggested by Dr. Bull, as the condylar processes of the occipital bone were pressed upwards into the cranial cavity and in congenital cases the arch of the atlas was sometimes fused with the occipital bone. These were purely theoretical objections to Dr. Bull's suggested method. They would have to be tested.

The criterion that the tip of the odontoid process of the axis was not cut by Chamberlain's line (the line joining the posterior end of the hard palate to superior posterior edge of the foramen magnum) in normal people also led to difficulty in diagnosing early cases of platybasia. The tip of the odontoid is difficult to identify with certainty in lateral films of the neck and it might appear to lie just below the line or just on it.

It was in the congenital cases of platybasia, often associated with congenital deformities of the cervical spine, that the diagnosis was of most value, because in those cases the deformity of the bones led to pressure upon the spinal cord or interference with its arterial circulation and also gross encroachment on the posterior fossa of the skull, leading to syndromes resembling cerebellar tumour, syringomyelia and amyotrophic lateral sclerosis, which might be relieved by decompression of the occipito-atlantal region.

Dr. Colin Edwards: It has been pointed out in America (Walsh *et al.*, 1941) that the term "platybasia" has been used by anthropologists to denote obtuseness of the sphenoidal angle beyond 150 degrees. This platybasia, however, causes no symptoms and is not necessarily associated with the invagination of the foramen magnum and its surrounding areas which does produce neurological symptoms. To this invagination the term "basilar impression" has been given and it is this basilar impression rather than platybasia which invites the attention of neurologists.

Dr. Redvers Ironside said that the transverse and antero-posterior diameters of the skull were much increased in the cases that he had seen. The vertical diameter measured from the margin of the foramen magnum to the vertex of the skull was diminished. This was caused by softening of the base of the occipital bone, which became pushed upwards by the vertebral column on which it rested. The cranial fossæ sagged, as it were, round the foramen magnum. Platybasia was therefore a usual finding in such cases.

Affection of the Trigeminal Nerve Nucleus and Central Grey Matter of the Spinal Cord following the Administration of Stilbamidine.—Major P. Collard, R.A.M.C., and Professor S. Nevin, M.D.

B., male, aged 23. Serving soldier. Complaint: Numbness of face.

History.—In April 1946 whilst he was serving in Salonika he fell ill and kala-azar was diagnosed. In July 1946 he was given a course of stilbamidine injections, total with involvement of the platysma. Right facial weakness. Spoken voice heard at 2 in. on right and 2 ft. on left; bone conduction better than air conduction. Forward bowing of left arm and some weakness of right arm. The trunk and lower limbs were normal, but the gait was rather unsteady.

Wassermann reaction negative. X-ray of skull: Bones of the vault were markedly thickened, about 2½ cm. The region of the foramen magnum was invaginated giving the skull a mushroom appearance. This change in shape was due to invagination of the occipital condyles, and as a result of this invagination the anterior portion of the atlas was pushed up. The plane of the atlas relative to that of the hard palate formed an angle of 42 degrees, the normal relationship being roughly parallel, the plane of the palate being slightly above that of the atlas. The angle is clearly seen in fig. 1.

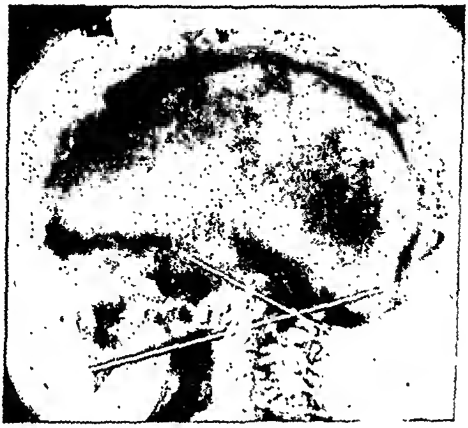

FIG. 1.

The appearances of the vault of the skull were characteristic of very advanced Paget's disease. All the bones surrounding the brain were involved, the disease process being most advanced in the frontal region where the new bone formation had a ray appearance suggesting the possibility of a sarcomatous degeneration. The bones of the face and both jaws were spared. The left humerus was the only other bone showing Paget's changes.

Mr. Wylie McKissock took a biopsy of the frontal bone.

Report (Dr. T. Crawford): The specimen shows bone trabeculæ with strands of cellular connective tissue infiltrating between them. There is active absorption of the trabeculæ going on and no laying down of new bone. The appearances are those of an osteitis deformans at an early stage. There is no evidence of sarcomatous change.

Observations.—The interest of the case was the complication of platybasia. Platybasia coming on in a previously normal-shaped skull—the acquired type—may be primary or secondary. The former group is the commoner, the cause is unknown and the texture of the bones of the skull is normal radiologically. Symptoms referable to the platybasia may or may not be present. The secondary platybasias, in which the cause is known, most commonly occur in Paget's skulls. (The author showed slides of three other cases which he had personally collected.) Theoretically any disease process involving softening of the occipital condyles might cause a secondary acquired platybasia, but apart from Paget's disease the author had only found a case of osteogenesis imperfecta in the literature. Platybasia may be commoner in Paget's disease than was formerly imagined and the early case may be more easily recognized by noting the plane of the hard palate relative to that of the atlas. The early case is not very easy to recognize, while the advanced case,

DISCUSSION ON HEALTH PROBLEMS IN GERMANY.

Colonel T. F. Kennedy: As Deputy Chief of the Public Health Branch of Supreme Headquarters, Allied Expeditionary Force, later as Director of Public Health (Civil Affairs) 21st Army Group and finally as Principal Medical Officer of the I., A. and C. Division of the Control Commission for Germany (British Element) I had the privilege of being able to follow the trend of events from the planning stage for civil health problems in the North-West European campaign to the completion of one year's occupation of our Zone in Germany.

I will start with the crossing of the Rhine and try to map out briefly the main measures which were taken to safeguard the health of the civil population and to prevent the spread of infectious disease.

Information had been received that typhus fever was more or less widely seeded throughout Germany. It was therefore necessary that we should have a plan to control the movement westward to their home countries of the vast numbers of displaced persons likely to be uncovered by the advancing armies.

It was decided that the main waterways traversing the country from north to south, in which the majority of the bridges would undoubtedly be destroyed, would form the best barriers. Control disinfestation centres were therefore set up at the following lines in succession: Rhine-Ijssel, Dortmund-Ems Canal, River Weser and River Elbe. The disinfestation centres were supplied with hand and power powder dusters and 10% D.D.T. powder was liberally dusted on all civilians presenting themselves at the crossings of these waterways.

The results obtained were amazingly good. A certain number of typhus-infected persons filtered through these barriers in the incubation period and developed the disease either *en route* or at their destinations. The passage of these cases was unavoidable short of instituting quarantine stations which was quite impracticable. Of about 1½ million displaced persons who were evacuated westward in the first few months the number of secondary infections, arising as a result in the liberated countries of Western Europe which received them, was surprisingly small.

We had put our faith in D.D.T. and it certainly proved to be a most effective weapon in the control of typhus. One recalls the devastating epidemics of typhus fever during, and after, the 1914-1918 war and one shudders to think what might have happened in Western Europe had we not had D.D.T. at our disposal.

A small public health staff was operating under 21st Army Group (Civil Affairs) whose duty it was to rehabilitate the Civil Health Administrations, and to give such help as was practicable to them, as soon as possible after territories were uncovered by the advance. These Public Health Officers were earmarked for their particular role in the Military Government of Germany, and were deployed to their respective stations as soon as possible so that when the fighting ceased the majority of them were already at their posts and had started work on the rehabilitation of the German Health Services.

The British Zone of Germany consists of the provinces of Schleswig-Holstein, Hanover, Westphalia and North Rhine provinces.

These provinces are divided into varying numbers of Regierungsbezirke which in turn are further subdivided into Stadt and Land Kreise.

We had British Public Health Staffs at Provincial and at Regierungsbezirk levels dosage 0·6 gramme. His kala-azar cleared up and he was quite well until the beginning of October 1946 when one morning he noticed numbness over the tip of his nose and upper lip. One day later the numbness had spread up to around the eyes, and three days later the whole face and forehead were numb.

When first seen on October 10, 1946, his general condition was good, and the only abnormal signs in the C.N.S. were found in the trigeminal nerve, as follows: Sensation: Dulling to pin-prick and impaired perception of light touch and heat and cold, in all three divisions of the fifth nerve on both sides: 2 point discrimination, deep pain, and vibration sense were intact. Motor n.a.d. Corneal reflexes present and equal. Jaw-jerk present.

Ten days later the sense of numbness spread down into the neck and over the back of the scalp the lowest dermatome affected being C3. Since then there has been a gradual improvement in that the sensory loss has become both less extreme and less severe.

Present condition.—Neurological signs are limited to the fifth nerve. Motor and reflex functions of this nerve are normal. The sensory disturbance is as follows: There is dulling to pin-prick and impaired perception of light touch in all three divisions on both sides, otherwise there is no abnormality.

Professor S. Nevin: There can be little doubt that the lesion in these cases is in the fifth nerve nucleus and in the central grey matter of the cervical spinal cord. We have here, then, another of these examples of selective action on the nervous system which are always very interesting, but very difficult to explain. The nuclei affected are the chief pontine nucleus and the descending nucleus, and the cells in these nuclei are different structurally from the mesencephalic root of the fifth nerve which appears to be intact, as is shown by the preservation of the jaw-jerk. The other interesting point is that the symptoms set in three months after the injections. How can this long latent period be explained? It is possible that the drug is fixed by the cells and that a toxic substance is liberated later by metabolic changes. It is perhaps possible that it is absorbed at the sensory nerve-endings and produces the lesion when it reaches the cell bodies.

Dr. J. W. Aldren Turner: This trigeminal neuropathy following the use of stilbamidine is common, so common that the use of the drug in the treatment of kala-azar has been prohibited in India Command. Stilbamidine is diamidino-diphenyl-ethylene, and it is probably the ethylene linkage which is important in the production of the trigeminal affection, as this radical is also present in trilene, which causes cranial nerve palsies at times, when it is used as an anæsthetic in a closed circuit. The other diamidine used in tropical medicine, propamidine, is also toxic to the nervous system and causes a peripheral neuritis but apparently does not affect the trigeminal nerve and there is no ethylene linkage in this compound.

In two personally studied cases of stilbamidine neuropathy there has been dissociated sensory loss in the trigeminal distribution, appreciation of pain and temperature being normal but light touch being impaired, which suggests that the lesion is in the principal sensory nucleus of the trigeminal nerve. In addition the patients had coarse involuntary twitching movements of the upper lip.

The President agreed with Dr. Aldren Turner that in India the condition was not uncommon. Napier and Sen Gupta (1942); Sen Gupta (1943) had met with it in 18 out of a total of 108 cases of kala-azar treated with this drug.

DISCUSSION ON HEALTH PROBLEMS IN GERMANY.

Colonel T. F. Kennedy: As Deputy Chief of the Public Health Branch of Supreme Headquarters, Allied Expeditionary Force, later as Director of Public Health (Civil Affairs) 21st Army Group and finally as Principal Medical Officer of the I., A. and C. Division of the Control Commission for Germany (British Element) I had the privilege of being able to follow the trend of events from the planning stage for civil health problems in the North-West European campaign to the completion of one year's occupation of our Zone in Germany.

I will start with the crossing of the Rhine and try to map out briefly the main measures which were taken to safeguard the health of the civil population and to prevent the spread of infectious disease.

Information had been received that typhus fever was more or less widely seeded throughout Germany. It was therefore necessary that we should have a plan to control the movement westward to their home countries of the vast numbers of displaced persons likely to be uncovered by the advancing armies.

It was decided that the main waterways traversing the country from north to south, in which the majority of the bridges would undoubtedly be destroyed, would form the best barriers. Control disinfestation centres were therefore set up at the following lines in succession: Rhine-Ijssel, Dortmund-Ems Canal, River Weser and River Elbe. The disinfestation centres were supplied with hand and power powder dusters and 10% D.D.T. powder was liberally dusted on all civilians presenting themselves at the crossings of these waterways.

The results obtained were amazingly good. A certain number of typhus-infected persons filtered through these barriers in the incubation period and developed the disease either *en route* or at their destinations. The passage of these cases was unavoidable short of instituting quarantine stations which was quite impracticable. Of about 1½ million displaced persons who were evacuated westward in the first few months the number of secondary infections, arising as a result in the liberated countries of Western Europe which received them, was surprisingly small.

We had put our faith in D.D.T. and it certainly proved to be a most effective weapon in the control of typhus. One recalls the devastating epidemics of typhus fever during, and after, the 1914-1918 war and one shudders to think what might have happened in Western Europe had we not had D.D.T. at our disposal.

A small public health staff was operating under 21st Army Group (Civil Affairs) whose duty it was to rehabilitate the Civil Health Administrations, and to give such help as was practicable to them, as soon as possible after territories were uncovered by the advance. These Public Health Officers were earmarked for their particular role in the Military Government of Germany, and were deployed to their respective stations as soon as possible so that when the fighting ceased the majority of them were already at their posts and had started work on the rehabilitation of the German Health Services.

The British Zone of Germany consists of the provinces of Schleswig-Holstein, Hanover, Westphalia and North Rhine provinces.

These provinces are divided into varying numbers of Regierungsbezirke which in turn are further subdivided into Stadt and Land Kreise.

We had British Public Health Staffs at Provincial and at Regierungsbezirk levels but not at Kreis levels. A Regierungsbezirk is roughly comparable to a County in England.

The work of these Officers in getting the German Health Services on their feet again was rendered very difficult by massive destruction of hospitals and public services which had been caused by the bombing and fighting, by the chaos which prevailed after defeat and capitulation, by the almost complete lack of communications and by the fact that the majority of the senior Public Health officials and other senior professional medical men had to be relieved of their duties on account of their Nazi associations. The result was that the inexperienced man of inferior professional capacity had to be relied on in the building up of the health services. There was, however, no shortage in numbers of doctors, and releases from the Wehrmacht of medical men often produced an embarrassing situation in which, in certain localities, there were more doctors than were required.

In spite of these difficulties slow but steady progress was made. There was a shortage of medical supplies and immediate steps were taken for priority to be given to the starting up of factories producing them.

Hospital accommodation was very inadequate. Many hospitals had been destroyed—many others seriously damaged. A comprehensive plan was drawn up to increase the number of hospital beds and, as a result, the number was raised from 0·8% of population to well over 1%, with provision for expansion by another 0·3% by the winter of 1945. This meant an increase of approximately 100,000 beds.

In the cities and larger towns serious disruption of the water and sewage installations was almost universally present. This required strenuous measures to prevent the occurrence and spread of water-borne diseases.

Reliable statistical data on the state of the health of the population were not available for some time after the occupation of Germany, due to the causes already mentioned, such as disorganization of the health services, loss of records and almost complete disruption of communications. It was evident, however, that tuberculosis had increased considerably during the war years, though its extent has not been definitely ascertained and, short of mass radiography, it is doubtful if it will be. Diphtheria was prevalent. The incidence in the British Zone for the last quarter of 1945 was from 80/100 per 10,000 per annum in the North Sea and West Baltic areas which include Berlin, Schleswig-Holstein, Hamburg, Bremen and Hanover. The rest of the British Zone was about half this rate. The average case mortality was 5·7%. Typhoid was also fairly widespread but the number and extent of epidemics were far less under the conditions prevailing than one had anticipated. A few sporadic cases of poliomyelitis occurred.

The main hazards of health might be summarized under the following headings: (1) Inadequate nutrition. (2) Lack of adequate accommodation owing to the enormous destruction of houses and to increase of population caused by migration from the East. (3) Massive destruction and damage to water and sewage undertakings.

The state of nutrition of the civil population was kept constantly under review and was the subject of repeated nutritional surveys. Practically all food was rationed and our aim was that the ration scale should at least provide the minimum food necessary for the bare maintenance requirements of health. This was laid down at 1,550 Cals. for the normal adult consumer. This scale was not reached during the first year of occupation of the British Zone. 1,250 Cals. was attained but this had to be reduced early this year to 1,050 at which scale it was when I left Germany in May 1946. I understand that it has since been increased to 1,250 Cals. and that it is hoped to reach a 1,550 Cal. scale before long.

In spite of this extremely low and inadequate ration scale there were few indications of serious deterioration in the nutritional health of the normal consumer. The only explanation I can offer for this is that the ration scale must have been considerably supplemented from one source or another.

There was, however, evidence of nutritional deficiency in institutions, where supplementation of the ration scale was difficult; in aged people and others who were unable to forage for extra food; and in children. There was also a considerable loss of weight in adults compared with twelve months previously. It was common to find men and women who had lost as much as 30 to 40 lbs. This is not surprising for the Germans were habitually overweight in pre-war days. Special ration scales were issued to children, adolescents, pregnant women, moderately heavy workers, heavy workers and very heavy workers.

It was always felt and constantly stressed that a diet sufficient for the normal requirements of the body must necessarily form the basis on which the general health of the population is founded.

The accommodation problem was governed by two main factors: (1) Increase in population. (2) Destruction of houses.

The total population of the British Zone in 1939 was approximately 20 millions. In September 1945 it was slightly more but the numbers of displaced persons to be repatriated would bring it down to about 20 millions again. In addition, plans had to be made for the reception of a possible 3¾ million refugees from the East.

In 1939 there were 5,459,000 dwelling houses in that part of Germany which is now the British Zone. Of these, approximately 2,000,000 were destroyed and 1,000,000 were damaged, leaving approximately 2,500,000 undamaged. Of the damaged houses about 600,000 were capable of being made habitable for the winter. The number of dwellings, therefore, capable of habitation during the winter of 1945-1946, was in the region of 3,000,000. If one allows 420 sq. ft. of living space per dwelling, the habitable houses in the Zone would permit of 53 sq. ft. of floor area per person for the projected population of 23,750,000.

Certain areas were tentatively earmarked as "Black Areas" in relation to the plan for the reception of refugees from the East. The earmarked areas were: (1) The whole area of the British Zone west of the Rhine. (2) The area of the Ruhr Regional Planning Authority. (3) The towns of Münster, Paderborn, Hanover, Wilhelmshaven, Emden, Hamburg, Lübeck, Neumünster, Kiel, Flensburg, Schleswig, Lütjenburg, Eutin, Lüneburg and Braunschweig.

The distribution of refugees from the East was thus based on a survey of the accommodation available and they were distributed on that basis.

One cannot leave the subject of accommodation without referring to the shortage of fuel for cooking and ordinary domestic heating. Owing to the diminished output of the coalmines of the Ruhr and elsewhere and the increased demands for reparation on such as was produced, no coal was allowed for domestic consumption to the civil population. The civil population had to make such arrangements as they could for the felling of timber and the collecting of wood fuel from the countryside. The result was that in the majority of cases it was difficult to obtain sufficient fuel for cooking and little was available for domestic heating.

With such a bleak prospect in regard to accommodation it was doubly necessary to increase hospital beds throughout the Zone to a figure which might be capable of dealing with the number of patients which might reasonably be expected from a population badly housed and insufficiently fed. The increase of hospital beds, previously mentioned, of 100,000 was consequently effected. The manufacture and distribution of essential medical supplies were speeded up and stocks of one month's requirement of these were accumulated at selected centres so that they might be readily available in an emergency. Medical, nursing and auxiliary personnel were earmarked for their respective duties and in each Regierungsbezirk 5% of doctors and trained nurses were specially earmarked to be formed into mobile teams of 1 doctor and 3 trained nurses for emergency service in any part of the Zone. These teams were to be provided from local resources, with a scale of medical equipment but not at Kreis levels. A Regierungsbezirk is roughly comparable to a County in England.

The work of these Officers in getting the German Health Services on their feet again was rendered very difficult by massive destruction of hospitals and public services which had been caused by the bombing and fighting, by the chaos which prevailed after defeat and capitulation, by the almost complete lack of communications and by the fact that the majority of the senior Public Health officials and other senior professional medical men had to be relieved of their duties on account of their Nazi associations. The result was that the inexperienced man of inferior professional capacity had to be relied on in the building up of the health services. There was, however, no shortage in numbers of doctors, and releases from the Wehrmacht of medical men often produced an embarrassing situation in which, in certain localities, there were more doctors than were required.

In spite of these difficulties slow but steady progress was made. There was a shortage of medical supplies and immediate steps were taken for priority to be given to the starting up of factories producing them.

Hospital accommodation was very inadequate. Many hospitals had been destroyed—many others seriously damaged. A comprehensive plan was drawn up to increase the number of hospital beds and, as a result, the number was raised from 0·8% of population to well over 1%, with provision for expansion by another 0·3% by the winter of 1945. This meant an increase of approximately 100,000 beds.

In the cities and larger towns serious disruption of the water and sewage installations was almost universally present. This required strenuous measures to prevent the occurrence and spread of water-borne diseases.

Reliable statistical data on the state of the health of the population were not available for some time after the occupation of Germany, due to the causes already mentioned, such as disorganization of the health services, loss of records and almost complete disruption of communications. It was evident, however, that tuberculosis had increased considerably during the war years, though its extent has not been definitely ascertained and, short of mass radiography, it is doubtful if it will be. Diphtheria was prevalent. The incidence in the British Zone for the last quarter of 1945 was from 80/100 per 10,000 per annum in the North Sea and West Baltic areas which include Berlin, Schleswig-Holstein, Hamburg, Bremen and Hanover. The rest of the British Zone was about half this rate. The average case mortality was 5·7%. Typhoid was also fairly widespread but the number and extent of epidemics were far less under the conditions prevailing than one had anticipated. A few sporadic cases of poliomyelitis occurred.

The main hazards of health might be summarized under the following headings: (1) Inadequate nutrition. (2) Lack of adequate accommodation owing to the enormous destruction of houses and to increase of population caused by migration from the East. (3) Massive destruction and damage to water and sewage undertakings.

The state of nutrition of the civil population was kept constantly under review and was the subject of repeated nutritional surveys. Practically all food was rationed and our aim was that the ration scale should at least provide the minimum food necessary for the bare maintenance requirements of health. This was laid down at 1,550 Cals. for the normal adult consumer. This scale was not reached during the first year of occupation of the British Zone. 1,250 Cals. was attained but this had to be reduced early this year to 1,050 at which scale it was when I left Germany in May 1946. I understand that it has since been increased to 1,250 Cals. and that it is hoped to reach a 1,550 Cal. scale before long.

In spite of this extremely low and inadequate ration scale there were few indications of serious deterioration in the nutritional health of the normal consumer. The only explanation I can offer for this is that the ration scale must have been considerably supplemented from one source or another.

nucleus of representation of the health services in the British Zone in a central Health Administration for the whole of Germany if and when such an administration eventualizes.

In Berlin a quadripartite Health Committee was set up which dealt with such health problems as were common to all the four Zones, British, American, Russian and French. Information on health matters was also exchanged at this level.

Any reference to the work which has been carried out on health in Germany would be incomplete without a warm tribute to the sound planning carried out by the Health Branch of S.H.A.E.F. under Major-General Warren F. Draper, C.B.E., of the United States Army, to the whole-hearted, self-sacrificing and most efficient service rendered by the personnel of the Health Branch of the Control Commission, and to the invaluable assistance which was given to us by the Army Medical Services under Major-General Sir Edward Phillips, K.B.E., without whose help in the early days we could not have succeeded in our task.

Dr. P. G. Horsburgh (*late Lieut.-Colonel, R.A.M.C.*): *Berlin at the time of occupation.*—Before entering Berlin we had information as to the portion we were to control. Berlin would be divided into three roughly equal parts, to be occupied by the U.S.A., U.S.S.R. and ourselves: the population of each was approximately 1 million.

It should be appreciated that Berlin was over 100 miles from the British Zone of Germany. It was completely isolated in the Russian Zone except for the autobahn for military traffic and a single line railway which was under Russian control—the second track having been pulled up by the Russians for some unknown reason. The lack of communication with our Zone made for difficulties of supply, such as food, drugs, &c.: German civilian transport required Russian permits which were nearly impossible to obtain for the first three months of our occupation.

We are here only concerned with the medical section of the Military Government. This was, on entry, the smallest section in number of any section of Military Government, consisting of myself and one gunner (a clerk). This was, fortunately, rectified in a few weeks time after the appalling conditions and problems were realized by the powers that be.

One did not require to be a medical man to appreciate the very bad state of health of the Berlin people, even allowing for the bombing and fighting that had gone on in the city. In no area I had been in, such as the hard-hit Ruhr, had people shown such malnutrition. These conditions were obvious on entering the city.

Our first job was to contact our allies. The U.S.A. Health Section was well known as we had been working together in other areas. The Red Army were unknown. It took some time to make contact with our Soviet opposite numbers. The first attempt is too long a story to relate here, suffice to say we learnt the Russian word "no"—with a sub-machine gun pointing at us in a most disconcerting manner.

After some days we did create a joint meeting of the Allied Public Health Officers. These meetings were long and difficult owing to the distrust shown at first by the Red Army. Our first difficulty, for example, was that the water supply, being greatly contaminated, had to be made safe. The water supply to Berlin is from shallow wells fed from the lakes round the city. The water is filtered by sand filters, but not as a whole chlorinated. There were some three to four thousand major breaks in the water system and two to three thousand in the sewage system. The electricity supply was very intermittent, causing failure in the pumps with a loss of water pressure and in fact causing negative pressure. It was suggested that all water should be heavily chlorinated in the whole of the city. U.S.A. agreed, but to our astonishment the Russians refused point blank to agree to a general order. They maintained that an order to the Germans should be made to obtain a pure which was based on the minimum requirement for the treatment (either hospital or domiciliary) of 100 patients for one week.

The winter of 1945-1946 passed, fortunately, without any serious epidemic but the hospital situation throughout the Zone had been placed on a sound footing, capable of meeting any ordinary demands, and the handing over by the British Military Authorities to the German Civil Authorities of all the Wehrmacht patients and hospitals provided still more hospital accommodation.

The immigration of refugees from the Russian Zone and from that part of Germany taken over by Poland presented serious problems in controlling the introduction of infectious disease. Certain refugee reception centres were set up at selected points on the frontier between the British and Russian Zones. At these centres refugees were fed, given ration cards, medically inspected and dusted with D.D.T. powder.

It was quite impracticable to install an effective barrier all along the frontier so reliance had to be placed on making it to the advantage of the refugees to come through the selected centres. The provision of shelter, food, ration cards and onward transport to their destinations provided the necessary attraction and very few refugees crossed the "green" frontier between the centres.

The responsibility for medical examination of the refugees, hospitalization, segregation and dusting with D.D.T. was put on the German Health Services under the general supervision of the British Public Health Staffs.

Courses of instruction in D.D.T. dusting had been set up in each Province for German personnel and eventually every Stadt and Land Kreis had persons trained in the technique and had the equipment necessary for carrying out the dusting.

By this means all refugees arriving at the frontier were dusted and they were dusted again on arrival at their final destination within the Zone. Any cases of typhus imported during the incubation period were promptly and adequately dealt with wherever they occurred, contacts were dusted, and secondary infections were kept at negligible proportions.

The extensive damage to water and sewage installations in the cities and larger towns was such a potential hazard to health that early priority was given to their repair and every effort was made to provide the raw material necessary. Immediate steps were taken for super-chlorination of water supplies to be carried out so as to ensure that available chlorine was always present in the water delivered at all distribution points on the supply system. These measures were effective and I am aware of only two instances in which outbreaks of disease—both enteric—were considered to be due to water-borne infection.

During the first few months after occupation the responsibility for rehabilitation and direction of the German Health Services necessarily devolved on the British Public Health Staff of the Control Commission but the policy was that this responsibility should gradually be handed over to the Germans themselves as soon as they were in a position to assume it. Our officers at Provincial and Regierungsbezirk Headquarters dealt with the German Health Administrative Officers at these levels and the administrative channels for instruction and information passed through them. In this way control and intimate contact with German Health Administration in the field were effected but the executive work was the responsibility of the Germans themselves. In order to promote the handing over of responsibility to the Germans a German Zonal Advisory Committee on Public Health was formed of representatives of each of the Provinces within the Zone and it gave valuable assistance to the Public Health Staff of the Control Commission on the many problems put before it, including the control of the medical and nursing services, medical and nursing education, medical supplies and distribution, venereal disease, &c.

This Committee remained advisory up to the time I left Germany but it was hoped that it would eventually be given executive powers and that it would form the nucleus of representation of the health services in the British Zone in a central Health Administration for the whole of Germany if and when such an administration eventualizes.

In Berlin a quadripartite Health Committee was set up which dealt with such health problems as were common to all the four Zones, British, American, Russian and French. Information on health matters was also exchanged at this level.

Any reference to the work which has been carried out on health in Germany would be incomplete without a warm tribute to the sound planning carried out by the Health Branch of S.H.A.E.F. under Major-General Warren F. Draper, C.B.E., of the United States Army, to the whole-hearted, self-sacrificing and most efficient service rendered by the personnel of the Health Branch of the Control Commission, and to the invaluable assistance which was given to us by the Army Medical Services under Major-General Sir Edward Phillips, K.B.E., without whose help in the early days we could not have succeeded in our task.

Dr. P. G. Horsburgh (*late Lieut.-Colonel, R.A.M.C.*): *Berlin at the time of occupation.*—Before entering Berlin we had information as to the portion we were to control. Berlin would be divided into three roughly equal parts, to be occupied by the U.S.A., U.S.S.R. and ourselves: the population of each was approximately 1 million.

It should be appreciated that Berlin was over 100 miles from the British Zone of Germany. It was completely isolated in the Russian Zone except for the autobahn for military traffic and a single line railway which was under Russian control—the second track having been pulled up by the Russians for some unknown reason. The lack of communication with our Zone made for difficulties of supply, such as food, drugs, &c.: German civilian transport required Russian permits which were nearly impossible to obtain for the first three months of our occupation.

We are here only concerned with the medical section of the Military Government. This was, on entry, the smallest section in number of any section of Military Government, consisting of myself and one gunner (a clerk). This was, fortunately, rectified in a few weeks time after the appalling conditions and problems were realized by the powers that be.

One did not require to be a medical man to appreciate the very bad state of health of the Berlin people, even allowing for the bombing and fighting that had gone on in the city. In no area I had been in, such as the hard-hit Ruhr, had people shown such malnutrition. These conditions were obvious on entering the city.

Our first job was to contact our allies. The U.S.A. Health Section was well known as we had been working together in other areas. The Red Army were unknown. It took some time to make contact with our Soviet opposite numbers. The first attempt is too long a story to relate here, suffice to say we learnt the Russian word "no"—with a sub-machine gun pointing at us in a most disconcerting manner.

After some days we did create a joint meeting of the Allied Public Health Officers. These meetings were long and difficult owing to the distrust shown at first by the Red Army. Our first difficulty, for example, was that the water supply, being greatly contaminated, had to be made safe. The water supply to Berlin is from shallow wells fed from the lakes round the city. The water is filtered by sand filters, but not as a whole chlorinated. There were some three to four thousand major breaks in the water system and two to three thousand in the sewage system. The electricity supply was very intermittent, causing failure in the pumps with a loss of water pressure and in fact causing negative pressure. It was suggested that all water should be heavily chlorinated in the whole of the city. U.S.A. agreed, but to our astonishment the Russians refused point blank to agree to a general order. They maintained that an order to the Germans should be made to obtain a pure water supply. This was not done from lack of knowledge, but because it involved the U.S.S.R. getting from either U.S. or ourselves chlorine of which they had none. The difficulty was got over and the water was chlorinated. This small argument lasted three weeks.

The Military Government became greatly improved on the formation of a body, known as the Kommandatura, consisting of Commandants of each Allied power and the necessary Committee of each function working under them. This Committee (in our case the Public Health Committee) passed recommendations to the Commandants and they passed orders to the German Magistrat.

The German administration was left unchanged by the Allied powers. The Magistrat of the City includes a Public Health Department headed by a Medical Officer of Health.

The City is divided into 20 districts or Bezirke each with a Burgomaster and its Health Department. These have not the power of a London Borough, as they come under the general control of the Magistrat and do not raise a separate rate.

I would remind you that the City had capitulated to the Red Army on May 2, consequently the German Officers at the Magistrat and the districts on our entry were holding posts with Russian consent.

Of the six districts we took over, all Medical Officers of Health, except one, had been appointed, not for their ability but for their political views: suffice it to say that one was not even a medical man and another had "done time" for illegal operations. Drastic action was immediately taken and one month after British Military Government was established efficient medical officers were in each district of the British Sector.

Although British troops moved in on July 4 British Military Government did not take over its sector till July 12, 1945. During this time one found certain conditions, namely: (1) Polluted water supply. (2) Sewage system—20% going into sewage works only. 80% flowing into rivers and canals in the centre of the city. (3) Major epidemics of dysentery. (4) Shortage of medical supplies, some large hospitals having as little as one pint of ether and no sulphonamide. (5) Inadequate food supplies, no salt, and ration cards not being honoured. (6) High V.D. rate. (7) Major fly nuisance. (8) Shortage of hospital beds, 5,000 for the area, 50% of which were unfit for use in rain or cold.

These conditions applied to the city as a whole and should obviously be treated by uniform measures. These uniform measures should have been taken by agreement of the Allied Public Health Committee. (At the end of August the French took over a portion of the British Sector, and the committee then became quadruplicate.)

The hospital problem gave us great concern. As already mentioned, we had some 5,000 beds in our area, all the hospitals being damaged to a major degree. To increase the number of beds, repairs had to be pushed forward and other new buildings utilized by repairs and conversions. With the great help of the R.E.s attached to Military Government a special German Labour Force was brought in from the Zone and hospitals were put on No. 1 repair priority. The difficulties were many but were overcome; for example, glass was just not available. We found, however, that the Central Store of X-ray Films of the Insurance Organization of Germany was housed in Berlin in the British Sector and practically undamaged. Although these were valuable records I considered it more important to have them cleaned and use them instead of glass. These were used, but before we could utilize them we had to fly in nails as there were no nails in the city. It is interesting to record that every hospital of any size had a deep operating theatre block and beds for 6 or 7 patients, and in no instance did we find one of these deep units damaged by bombs. The Germans had in Berlin large surface air-raid shelters (bunkers). These could house some thousands of people, they were 4- to 5-storey structures with 7 feet reinforced walls, air conditioned and lifts to all floors. These had withstood the bombing and we converted one into a very good 3 to 4 hundred-bedded hospital. By the time Colonel Raeburn and I left Berlin in April we had over 9,000 weatherproof beds in operation, and emergency accommodation for 2,000 beds which could have been equipped and staffed in ten days if required. The staffing of the hospitals was not a difficult problem. We had in the British Sector a higher proportion of medical men than the other sectors.

On the de-nazification of the medical profession we are open to criticism. We did not pursue this problem with that energy that occurred in the other sectors. It was feared that Berlin might become more of the plague spot than it already was. We had orders to be ready for the "battle of the winter". No definite de-nazification law had been agreed till this year. I thought it best to get rid of the real red-hot Nazi, but not the nominal members. The U.S. were quite ruthless in getting rid of the nominal members, with the result they had great difficulty in staffing hospitals, domiciliary treatments, &c. When the de-nazification law was agreed they had to reinstate medical personnel that they had previously debarred from practice. We were, I think, justified in our more moderate action.

The question of domiciliary treatment of the German civilian caused difficulties, not from the point of view of numbers of doctors, but from the point of transport. The number of cars available for doctors in the British Sector was in the region of 10. It was obvious that doctors could not visit their normal districts. We, therefore, divided the British Sector into small districts by which it was possible for the doctor to walk to the patients.

Transport, or lack of it, caused difficulties in admitting patients to hospital. We had 7 ambulances of ancient vintage and 4 in the Russian Sector, i.e. 11 ambulances for 3 million population. Patients had to be taken to hospital in hand carts, horse vehicles, and the like, many dying before their arrival.

This difficulty was overcome by bringing into Berlin 20 ambulances from the Zone, 16 of which were ex-German army ambulances and 4 new British vehicles. These ambulances could not be used in the Russian Sector as permits could not be obtained from the Red Army. The treatment of patients, both surgical and medical, was a major difficulty on account of shortage of drugs, dressings, &c. The medical supplies in all hospitals and for general practitioners were such that much unnecessary suffering and loss of life were taking place. The death-rate was estimated to be in the region of 60 per thousand of the population and the infant mortality rate about 300 per 1,000 live births. These estimated figures may possibly be on the low side.

Sulphonamides were practically non-existent, even in the hospitals. Anæsthetics also were so short that surgeons had in many cases to stop, or drastically curtail their work. We endeavoured to get an agreement with our Allies as regards getting medicaments into the city. The Russians would not agree to work this on a city-wide level. The position was so acute it was decided by U.S. and ourselves that we would each bring in medicaments for our own sectors—an unsatisfactory arrangement but the only one which could be carried out quickly. It was decided in British and U.S. Sectors to set up medical stores and such a store was forthwith set up in the British Sector with a German Staff.

Owing to the extensive black market in drugs (U.S. penicillin one ampoule would fetch £75) it was decided to issue only to the hospitals in the British Sector. The amount of drugs brought in by December was something over 500 tons. The hospitals by November were well supplied with drugs and it was thought advisable to allow dispensing of private practitioners' prescriptions at the hospitals, when the drugs could not be obtained through chemists. A certain intermittent supply of drugs was coming into the city, through normal trade channels, by November 1945.

water supply. This was not done from lack of knowledge, but because it involved the U.S.S.R. getting from either U.S. or ourselves chlorine of which they had none. The difficulty was got over and the water was chlorinated. This small argument lasted three weeks.

The Military Government became greatly improved on the formation of a body, known as the Kommandatura, consisting of Commandants of each Allied power and the necessary Committee of each function working under them. These conditions applied to the city as a whole and should obviously be treated by uniform measures. These uniform measures should have been taken by agreement of the Allied Public Health Committee. (At the end of August the French took over a portion of the British Sector, and the committee then became quadruplicate.)

The hospital problem gave us great concern. As already mentioned, we had some 5,000 beds in our area, all the hospitals being damaged to a major degree. To increase the number of beds, repairs had to be pushed forward and other new buildings utilized by repairs and conversions. With the great help of the R.E.s attached to Military Government a special German Labour Force was brought in from the Zone and hospitals were put on No. 1 repair priority. The difficulties were many but were overcome; for example, glass was just not available. We found, however, that the Central Store of X-ray Films of the Insurance Organization of Germany was housed in Berlin in the British Sector and practically undamaged. Although these were valuable records I considered it more important to have them cleaned and use them instead of glass. These were used, but before we could utilize them we had to fly in nails as there were no nails in the city. It is interesting to record that every hospital of any size had a deep operating theatre block and beds for 6 or 7 patients, and in no instance did we find one of these deep units damaged by bombs. The Germans had in Berlin large surface air-raid shelters (bunkers). These could house some thousands of people, they were 4- to 5-storey sary interference by occupying powers are able to cope with any emergency that may arise. In my opinion the Germans are quite capable of re-establishing their Medical Services without large numbers of British personnel supervising their activities.

Dr. H. A. Raeburn (*late Lieut.-Colonel R.A.M.C.*): Colonel Kennedy has dealt with the varying situations met in Germany from the time British troops first crossed the Rhine. Dr. Horsbrugh has described the special political circumstances in Berlin—emphasizing the chaos and malnutrition. I will try to say something on another general matter—that of refugees—and refer to some of the more strictly medical problems, but before doing so I cannot resist mentioning one lesson driven home during our time in Berlin—the basic importance of environmental hygiene. In the early days even an increasing tuberculosis rate seemed of rather academic interest compared with faulty water mains and sewers.

The large-scale movements of population which followed the end of hostilities have already been mentioned by Brigadier Kennedy. In Berlin there were few displaced persons but the problem of the German refugees soon became acute.

You will already have appreciated that Berlin was rather like an island in a Russian sea. For practical purposes all refugees came from the East—the Russian Zone of Germany, and ceded territory—and were made up of three classes. A few were Berlin residents returning, and Germans evacuated from the West on their way home, but the vast majority were the inhabitants of the ceded territories. In theory there was some sort of agreement on the orderly evacuation of the refugees, but as far as Berlin was concerned, they seemed to arrive in the most haphazard fashion. Another theory was that refugees were not permitted to enter Berlin at all, but in practice, in October and November, they came at the rate of 20,000 per day. The difficulties can be imagined when I say that one temporary camp set up for 1,500 refugees had to accommodate 8,000. I suppose these people found themselves in a countryside where food and shelter were lacking, and the natural tendency was to make for a big city where, in their utter misery, they might expect some help. Most roads and railways from the eastern provinces passed through Berlin, and a common sight during the autumn of 1945 was crowds of refugees leaving the railway stations and coming from the eastern part of the city into our sector. The lucky ones were pulling their belongings along in carts, the more unfortunate carrying them on their back. They arrived by train and on foot. Trains were crammed and at one station in one month 100 dead bodies were found on arrival. Many had had little food for a number of days and had been subject to much maltreatment. One particularly troublesome condition was lacerated feet, which were slow in healing in the debilitated people.

One particular incident sticks in one's memory. One evening we heard that a barge with 200 children had arrived. They were a Lutheran children's home from Stettin, who had been suddenly turned out of their premises. For want of anything better they moved to a barge which for lack of any other place to go came to Berlin. The children had hardly any food for the three weeks' journey and they had to be kept in bed in the holds as there was no level deck; 5 died of starvation. The nursing sisters did a fine job and everything was spotlessly clean. One did not have to be very sentimental to be touched by the way the children were kept occupied by singing some of the very charming North German folk songs. We managed to put this home into a school in Berlin. The person who was most relieved to see the children fixed up was the barge skipper, who I think was afraid he might be pressed into service as a children's nurse. With better feeding they soon improved although 20 had to be admitted to hospital and they ultimately went to the British Zone.

It was found, however, that this dispensing of prescriptions for private practitioners' cases led to black-market selling of British drugs and had to be stopped. Active measures were taken to get chemists' shops supplied through the normal trade channels, for use of practitioners.

What of feeding the city? On taking over Military Government, Britain also took on the responsibility of feeding the civilian population in their own sector. It was agreed that all foodstuffs should be brought to a central depot and distributed through the Magistrat. This was done because only certain foods were available from certain Zones. No agreement could be made for the normal larder of the city to be used as this was in the Russian Zone.

In order to bring in her quota of food Britain had to transport this some hundreds of miles on a far from efficient rail system.

The early days of occupation left the German people very short of food. In theory the following rations were available to the people:

Heavy workers	2,443 Calories	Children under 15	1,500 Calories
Workers..	1,957 Calories	Non-workers (including housewives, expectant mothers) ..	1,200 Calories
Sedentary workers	1,581 Calories		

In the early days, ration cards were seldom honoured to the amount allowed. Germans employed in the offices of Military Government were on No. 2, i.e. 1,957, but the amount they obtained was probably less than 1,000. One found in our own office girls fainting at the desks and the ones that carried on were in such a poor state of health that little concentration for work was possible in the afternoons. Their state of health was so bad we had to give them a midday meal in order to get the work out of them. The meal was roughly 300 calories.

The No. 5 class (1,200) was called the "death class". This was very true where it was the only source of food. For example, in the prisons all prisoners were on No. 5 rations. These were, in fact, getting less than 1,000. The prisoners were in such a state that no hard labour was carried out. Hunger œdema was rife. Prisoners who got to the stage of hunger œdema did not last more than one or two weeks before they died. No adequate diet was available in the prison, or, in fact, in the general hospitals for the treatment of the prisoner with hunger œdema.

Rations for the population were seldom up to date in July, August and September. We were for two months without fat rations. In September, a British Nutritional Team visited the city and reported that the nutritional state of the people of Berlin was the worst in the British occupied area of Germany.

The Public Health Section recommended in the early stages that No. 5 ration should be abandoned. This was eventually adopted, first in the prisons and then for the population as a whole. The amount of black-market food available was small and at such a price (£20 for one kilogram of butter) that it was not a factor in the general health of the population.

Six months after the occupation by the British, all ration cards were regularly honoured and the general state of health of the Berliner so improved that the winter did not cause the anxiety which was feared. We went through the winter without undue major epidemics.

The rations after six months had been increased for the class 4 children (1,300 to 1,500 Cals. + milk) and class 5 ration increased to 1,500 Cals. and these were being honoured. Hospital patients and expectant mothers got ½ litre milk *per diem*. Additions of cod-liver oil were issued to children under 5 years. One can say that Berlin was the worst-fed area in the British Zone in July and was probably the best-fed at the beginning of 1946 as they did not suffer the cuts in the rations this year that occurred in the other parts of the British Zone.

In conclusion may I say that in my opinion the German Medical Services in Berlin were adequate and efficient when I left in April, and if left without unnecesspoke with a number of German clinicians and I think it must be agreed that some people, incubating the disease, were killed by this measure. One physician made a curious observation that the disease itself seemed to be as severe in the inoculated, but that complications were less frequent. It must be emphasized that large numbers of refugees were expected, and that benefits ought to show themselves in the spring and summer of 1946. In actual fact, enteric has been much lower this summer—the average was 50 cases per week.

Typhus.—Control of typhus was, I think, a triumph of preventive medicine. Apart from the fact that Germany's surrender took place in the summer, the stage seemed to be set for an epidemic. No epidemic occurred, although there were some 284 cases in the city (37 in the British Sector), for the six months July 1945 to January 1946. The first cases appeared in August and there was a considerable number by the end of October. I had an opportunity of seeing practically all the cases in the British Sector and a considerable number in other sectors. So far as one could determine, all cases in the British Sector, with one exception, were infected elsewhere. The exception is of interest. This case occurred in a nurse who had received anti-typhus inoculations with the mouse lung vaccine. This vaccine was subsequently withdrawn as it was found to be ineffective.

The control depended essentially on the louse control of refugees. The necessary equipment and supplies were obtained from British sources and a British Hygiene Section in Berlin supplied N.C.O. instructors, who trained German personnel. Mass dusting of the whole population was not considered necessary as the German is naturally clean. Anti-typhus inoculation was given to doctors, nurses and others connected with the sick and refugees. Clinically, rashes were not marked, the "typhoid state" and lineal injection of the conjunctiva being the most striking symptoms.

Venereal disease.—This problem was of special importance owing to the high incidence among British troops. Conditions were ideal for its spread. There had been the usual wartime increase. With the fall of the city, administration had broken down and there was separation of families, often without news of each other and the city was full of refugees and foreign troops. Destitution and prostitution were rife. One officer summed up the situation somewhat cynically with the remark: "Few morals could withstand a tin of sardines." It is certainly true that many women were driven to prostitution owing to lack of food and the disease was found in all grades of society. Coupled with this there were inadequate treatment facilities, sulphonamide being especially short.

One cannot give the incidence with any certainty. In one district a survey revealed that 10% of women between the ages of 15 and 45 admitted suspicious symptoms. The Berlin M.O. put the figure as high as 40% of the female population.

The measures taken were designed to trace infected women and improve treatment. As you may know, when a British soldier is infected, he is asked to supply particulars of the possible source. Women infecting Allied troops were detained until free from infection, a special hospital being set apart for this purpose. When this work got properly organized, some 80 to 90% of reported contacts were traced. It says much for the versatility of the British "other rank" when I tell you that this job of tracing contacts was organized by two Military Police N.C.O.s—one an East End hawker and the other a goods porter from near Bristol. Their jeep, very much overloaded with persons being brought in for examination, was one of the sights of Berlin.

A variation was the raid on the black spot. Berlin has its notorious cafés like any other city, and scrutiny of confidential reports revealed where "picking up" was taking place. Briefly, the café or area was surrounded by the German police

It was impossible to patrol the city boundary effectively and I think it must be said that the Russians who controlled the eastern part of the city seemed to show very little interest in the matter, their attitude being "the Red Army has forbidden any refugees to enter, therefore there are none".

When faced with such misery, the British reaction is to do something, even though by doing so the difficulties were increased as more refugees were attracted. Soon the number of refugees in the British sector was much greater than in the rest of the city. Camps were set up by the "Refugee and Displaced Persons Section of Military Government" and the luckier refugees found accommodation there. The stream died down by the end of the year and by that time we had a more or less permanent camp with adequate accommodation for 10,000 persons.

At the peak it was a bit of a mystery where the majority of the refugees went. They seemed to find accommodation in cellars and only appeared when there was a possibility of their being evacuated to the British Zone in the West. It was realized that Berlin might become a plague spot, and arrangements had to be instituted to prevent infection spreading West. Before evacuation, refugees had a medical examination to assess fitness for travel, and a quick inspection before boarding trains or buses to eliminate infectious disease; they were deloused with D.D.T. and these measures were effective.

Another interesting movement was the return of German prisoners of war from the East. Their transport was the responsibility of the British Military Authorities but we had to arrange for a hospital for the reception of their sick. Sepsis due to undressed wounds caused most of the admissions. What one remembers of this hospital is the all-pervading smell of pus. It made one realize what Medicine owes to Lister.

It is against such a background that the question of epidemic disease has to be considered. Dysentery was the chief disease met with on arrival and in July 1945 there were some 2,000 notifications per week. The insanitary conditions of the city gave every opportunity of spread. It was impossible to do complete bacteriological examination of all cases but the few German laboratories working found that the disease was largely of the Flexner type. Of interest is the high fatality rate, 28%, which could be attributed to the general debility of the population, the lack of suitable drugs and the impossibility of dieting. Some cases seemed just to die. Pathologists reported that at a post-mortem they could recover the organism, but the bowel showed no inflammatory reaction: the patient had no power to resist.

Enteric was the disease which caused most anxiety. On our arrival in July it was known this disease was occurring—some 70 cases per week—but in the latter part of August the situation became alarming, the number of notifications reaching over 700 a week—mostly true typhoid. This rise coincided with an influx of refugees from Eastern Europe and it was estimated that 80% of the cases were imported. Hospitals were crowded and many cases had to be treated in unsatisfactory homes. In all, 12,700 cases with a fatality rate of 12% occurred in the city from July 1945 to January 1946. From the remarks on refugees you will have gathered we had no official information about conditions in the areas from which the refugees came—if rumours could be believed many villages were immobilized by the disease and cases were left lying in the street: also we had no control until the refugees arrived in the British Sector. In view of this, the drastic measure of compulsory inoculation was ordered and completed towards the end of September. The stamping of ration cards used by the Germans afforded an easy method of ensuring that people were inoculated and in actual practice over 90% of the population were immunized. One German M.O.H. asserted that inoculation was voluntary but people would get no food unless their cards were stamped!

One keeps an open mind as to the efficacy of this measure. It is true that the epidemic declined, but there would have been a seasonal decline in any case. One

Otology in School Children and Child Welfare

PRESIDENT'S ADDRESS

By H. V. Forster, M.C., M.B., Ch.B., M.Sc.

Those about to undertake the practice of Otology at the request of a local Education Authority will find special interest in the work of the late Dr. Kerr Love (1919) a Past President of this Section. This is a record of three years' work in the treatment of ear disease undertaken for the Glasgow School Board between the years 1912 and 1915. It is, to quote the author's words: "Essentially an essay on the Prevention of Deafness. Before the ink is well dried on its pages a Ministry of Health may be at work and it is the writer's wish that the progress of the new service will be such as soon to render the teaching of the book out of date.

Kerr Love was also asked for his advice on the treatment of ear disease in the schools under the control of the Secondary Education Committee of the county of Dumbarton, though the chief object of the Committee was to have cases of tonsils and adenoids treated by operation. My own work in Lancashire in the year 1919 was also started by a request to perform these operations and many others, no doubt, have had the same experience. We all have probably given the same answer, namely that we should be offered facilities to examine the candidates for such operations and discuss their indications, at the same time recording our observations on the condition of the ears, nose and throat.

I was well aware at the time that many operations were being done in this country upon the palatine and respiratory tonsils of school children for which the Ministry of Education had already granted certain facilities. Alison Glover (1938, *Proc. R. Soc. Med.*, 31, 1219) reminds us that the number of tonsillectomies officially recorded in public elementary school children for the year 1919 were for London, 11,817 and for England and Wales, 42,004.

Has this development in the practice of otolaryngology in school children gone far enough? Has ear disease been satisfactorily treated in the young?

A world war has descended upon us again laying bare the defects in our armour. The medical boards of the Ministry of Labour and National Service have been and still are busy examining the youth of the country and send to the otologist for his opinion the many cases of ear disease so often unconsciously tolerated and neglected by these young people no longer under the care of a school medical service.

Professor Canfield of Harvard (1945) showed an admirable colour film of the management of consultations in otolaryngology in a children's clinic in America. That, to me, was an example of how the work should be arranged. In my own, and the women who could not give an account of themselves or were known to the criminal police were detained and examined by the German Health Department. From September 1945 to January 1946 some 900 women were rounded up. Over a quarter were found to be suffering from venereal disease. In this way a considerable number of professional prostitutes were brought for treatment, though we probably did not find the respectable person forced into prostitution by destitution.

The next step was to try and improve treatment facilities. The German venereal disease scheme depends on the use of private physicians rather than public clinics. There was a great shortage of sulphonamide and arsenicals, but, sufficient supplies were obtained from British sources. These, however, did not completely solve the difficulty as sulphonamide had enormous value in the black market, 5s. to 7s. 6d. per tablet. It was felt that British drugs in such circumstances could not be handed out *ad lib.* We therefore got the German M.O.H.s to nominate doctors for each Bezirk and drugs were issued and accounted for by the number of cases treated. There was much inadequate treatment by black-market drugs, leading to sulphonamide-resistant cases.

Early this year, penicillin was made available in limited quantities for the treatment of persistent cases who had infected British troops. The venereal disease specialists in the British Military Hospitals trained German physicians in its use and a special hospital was set apart for this treatment, with satisfactory results. I must say that this penicillin caused us, as doctors, some heart-burning, as we had to limit its use to venereal cases, and to refuse it when it might have saved life.

Tuberculosis.—Being essentially a social disease, it is not surprising that the incidence of tuberculosis increased. Statistics were particularly difficult to obtain, but as far as we could find out the incidence per hundred thousand per annum had increased from 25·8 in 1938 to 48·9 for the six months July 1945 to January 1946. It was probably much higher. The tuberculosis question was early raised at the Kommandatura, but nothing much was decided. I hope you will not think us unappreciative of the tragedy of tuberculosis when I say that in the early months we thought the discussions rather academic; it seemed more important to concentrate on straightening out the general chaos and improving nutrition rather than to think of tuberculosis alone. Another point was, that little could be done. We did get some slight additions to the diet of the tuberculosis patient but the question of accommodation was difficult. Like other cities, Berlin's tuberculosis accommodation was largely outside the city. Travel difficulties made it impossible to send any patients to sanatoria in the British and American Zones in the West. A number of individual cases had travelled—or rather they were issued at our recommendation with travel permits. Frankly, we never knew what happened to them and one had an anxious feeling that giving a recommendation merely absolved one from the odium of doing nothing.

There was a large tuberculosis colony on the outskirts of the city in the Russian Zone of Germany, in use by the Red Cross. Our Russian opposite number did his best to recover some accommodation but could get no concession from his H.Q. The most we could do was to see that existing accommodation was used to the best advantage and improvise a few additional beds. I am glad to say that regular arrangements for the use of sanatoria in the West have been made.

Maternity and child welfare.—The Berlin set-up was essentially the same as our own. It so happened that the clinic buildings were usable and as most of the doctors were women the regular staff were available. Activities were handicapped by lack of supplies, but valuable educational work was done in instructing mothers in the best use of available food. The tragic infantile mortality reached of some 250 per thousand per annum might otherwise have been higher.

with its proper ventilation though moderate enlargement may not. We know that acute tonsillitis as part of an acute inflammation of the pharyngeal lining is sometimes associated with acute otitis media. Perhaps I am concerned with the fear that indiscriminate removal will do harm.

I do not like the term chronic tonsillitis for it may be argued biologically that it is a normal process but there will be no disagreement that removal of the palatine tonsil regardless of its size cures that disease named most suitably by Continental writers—"tonsillitis with free intervals" and with brilliant results in the health of the child.

The examination of the nasopharynx in children is difficult but a trial with the post-nasal mirror in every case gives excellent practice and many successes and I have given up long ago the digital examination of the post-nasal space in children except under general anæsthesia.

It will be agreed that in infections of the middle ear and interference with its proper ventilation, the hypertrophied and diseased respiratory tonsil of Luscha should be removed surgically. There are, however, numerous conditions within the nasal passages of children which do not benefit materially from this operation and one of these is allergic or vasomotor rhinitis which is by no means uncommon. It is sometimes associated with secretory otitis.

Some years ago Proetz (1931) described acute allergic middle-ear attacks difficult to distinguish from the early stage of acute suppurative otitis media and Koch (1946) recently published a cytological study of middle-ear secretions in which he discusses the so-called eosinophil chronic otites. There has been a call to our British Association of Oto-Laryngologists for closer co-operation between the pædiatricians and ourselves. I should especially welcome their help in the solution of the problem of the so-called catarrhs including catarrhal middle-ear deafness which is not to be dismissed as one of essential Eustachian obstruction.

Blegvad (1931) once asked the question: "Is it necessary to maintain as an independent malady the occlusion of the Eustachian tube?" a question discussed later by Holmgren (1931) when describing his experimental research on its function. War has added interest to the problem because of aviation pressure deafness, a subject which has been introduced here by Simpson and discussed in detail by McGibbon (1942) and I understand that treatment by radiation has now been used to relieve it. I have no experience of radium or radon therapy as applied to the nasopharynx in the middle-ear deafness of children in the manner of Crowe and Guild (1938). The well-tried manœuvre of inflation by Politzer's method gives brilliant if temporary relief in catarrhal otitis. Gone for a while is the depression of the drumhead and that strange grey translucent picture lightly coloured by a pink reflex from the tympanic wall. Some children are remarkably courageous to inflation but others are alarmed, perhaps there are members here to-day with memories of this experience in their own childhood and I have already remarked how fortunate we are that Nature alone does so much to relieve the growing child of his disability, but now and again we meet a striking case of the resistant Eustachian tube. I have in mind a boy of 7 years, his right ear successfully ventilated by Politzer's method in November 1930, but later without success. In January 1939 he retired at last from the unequal contest which had included several insertions of the Weber Leil intratympanic tube and one temporarily successful paracentesis. During those years, reluctantly disturbing the peace of his school holidays I had repeatedly observed a collection of fluid in his middle ear. Such difficulties recall to me a discussion opened here by Mollison (1934).

A depressing variety of middle-ear deafness is one where, in spite of rational medical and surgical treatment to the nose and nasopharynx the child remains examinations are made in the presence of the parent or some responsible deputy who is questioned in simple language about the child's complaints. In one clinic the school medical officer is also present. The form originally designed by Kerr Love makes a useful case sheet and, when completed, a permanent record to be filed and consulted again.

In their examination and treatment, the diseases of the outer ear do not call for special comment. But certain difficulties of management arise, as, for example, the case of keratosis obturans by no means uncommon in children. The study of the disturbances of the epithelial lining of the external auditory canal is our particular field of dermatology, but it is of importance also to us as surgeons for it leads to a better understanding of the behaviour of the epithelial covering which we hope will invade our operation cavities, those cavities of the hindmost end of the middle-ear cleft laid open by radical or modified radical operations in the surgical treatment of chronic suppurative disease.

THE PREVENTION OF DEAFNESS

In the prevention of deafness it is fortunate that syphilis in the future parent is better treated nowadays and we begin to understand how german measles infecting the pregnant mother may damage the auditory organ in the fœtus, but until the problem of the early development of otosclerosis has been solved it is in the treatment of suppuration and the so-called catarrhal conditions of the middle-ear system where so much can be done for the young.

In case-taking one finds many parents are deaf and in suppurative middle-ear disease I have seen repeatedly quite striking examples of a hereditary tendency.

There is some encouragement from the intermittent nature of childhood deafness, because we feel more hopeful of eventual recovery. Mother Nature, unaided, can do so much or we should find the hard of hearing more often in the adult population. Some years ago in Esthonia, E. Sarreste (1935) carried out researches in 1,366 pupils of schools in the city of Tartu. The ages varied from 7 to 20 years. He concluded that catarrhal otitis media diminishes with the age of the pupils and in the majority of children over 13 years of age there is less and less hope of improving the hearing. whereas below 13 years the greater number get well either spontaneously or as a result of rational treatment.

It is obvious that we must examine with specialist thoroughness the oropharynx, nose and post-nasal space and at once we are brought face to face with the tonsil problem.

Of the exact physiological significance of the palatine tonsils we remain uncertain. Schlemmer has insisted that they are an integral part of the pharyngeal lining and serve no separate functions. Glimstedt showed how the so-called germ centres, absent at birth, develop thereafter as a reaction to invasion from the outside world, and to Grossmann and Waldapfel (1926) we owe an understanding of what goes on in these centres during acute tonsillitis. Policed as they are during health by mononuclear cells, they are entered in times of acute bacterial invasion by the polymorphonuclear leucocyte in the pursuit of organisms. To destroy these organisms or prevent their development we now have the assistance of the sulpha group of drugs but on the other hand we know that they may curtail the recruitment of the granular leucocyte.

Torsten Skoog (1936) provides an attractive answer suggesting the theory that the lymphadenoid tissue of the pharynx has a sensitizing effect on the reticulo-endothelial system of the body.

What I should like to know is to what extent the palatine tonsil influences the health of the middle-ear cleft. Considerable hypertrophy presumably interferes

The child's ear provides special opportunity to observe the progress of moist defects of the membrana flaccida and the dry crusts which form in this area and to speculate, not without anxiety, what changes are taking place beneath them . . . I remember a publication by Marcus Diamant (1937). He believed that the otitic origin of cholesteatoma had not yet been proved and the title of his paper is in the form of a brief but significant question: "Acute or Chronic Otitis?"

What kind of major operation should be done to drain the middle-ear system in children to treat disease inaccessible to conservative measures?

I prefer to be kind to the tympanic contents after laying wide open the attic, aditus, the mastoid antrum and the attendant cellular system. One hopes thereby to retain more of the hearing function, but the tympanic lining has considerable powers of recovery whereas the parts behind invaded in due time by a foreign covering of squamous epithelium are subject to changes of complexion. Might I be allowed to suggest that the younger otologist will be saved much wounding of his *amour-propre* by remembering that squamous epithelium lies uneasily upon bone.

Very occasionally I have performed completely radical mastoid operations on both ears in the child and I think of one, now grown up, who has given useful service to her country in the A.T.S., though how this enthusiastic volunteer managed to slip through the net of medical inspection nowadays I cannot say.

What of the after-treatment of the mastoid operation for chronic middle-ear disease in children? I prefer to cut a Ballance's flap of the soft meatal tube but would not cross swords with those of my colleagues who prefer to leave it uncut. A lightly filled rubber finger-stall is inserted and later removed with little pain to a child. The late Sir James Dundas-Grant thought well of this method.

When dressings have been removed the ear is washed out once or twice daily with weak eusol and later with the mercurial lotion which serves well after discharge from hospital. I am not depressed by some temporary filling of the cavity by nature in the healing process.

Granulations of the meatus react well to the chromic acid bead and in time a layer of some depth recedes leaving epithelium on a hard seat. The child is now made safe, his general health improves remarkably and his morale has not been depressed by treatment of the ear with gauze packing.

In reading this Address I am aware that its teaching is elementary though supported inevitably by some experience provided by the passing of time, but we who practise medicine and surgery in this country are on the eve of great events. Our rulers are busy planning a comprehensive medical service for the nation and the problem of deafness has aroused fresh interest in high places. To help solve it we must begin with the child. I have no doubt that appeals by the otologist to develop his work for the children of the nation will be received with sympathy and that means will be provided to assure that it is well done.

deaf. The middle ear ventilates well and one cannot recognize through the drumhead any retained secretions or visible signs of adhesive processes. I am reminded, however, that the late Sir William Milligan speaking some years ago in this room expressed the opinion that the round window, placed as it is rather low in the tympanic wall is more readily exposed to pathological disturbances which eventually curtail its resilience.

SUPPURATIVE OTITIS MEDIA

In the treatment of acute suppurative otitis media we have had the opportunity at these meetings to discuss those newer aids, the sulpha group of drugs and penicillin.

If more children suffering from acute otitis were admitted to hospital and there had the assistance and proper control of the new therapeutics, no doubt the incidence of chronic suppuration would fall.

At the school clinic, however, it is most satisfactory to see so many discharging ears dry up and heal under simple conservative treatment, by which I mean irrigation with a suitable mercurial lotion followed by the instillation of alcohol drops and the pursuit of granulations with the chromic acid bead.

Lotion for Syringing:

℞	Mercuric chloride ..	4·375 gr.	(0·2838 g.)
	Sodium chloride ..	4·375 gr.	(0.2838 g.)
	Methyl violet	0·01 gr.	(0·00065 g.)
	Aq ad	℥ x	(300·0 c.c.)

Sig. A tablespoonful to be mixed with three tablespoonfuls of warm water and used for syringing out the affected ear.

See Solvellæ Hydrargyri Perchloridi in B.P.C. 1923, p. 1435, which gives methyl violet. I prefer this to the methylene blue of the later edition. The liquid is dispensed to avoid the danger of keeping mercurial tablets in the home.

Spirit Drops:

℞	Acid Boric	10 gr.
	60% Alcohol	℥ I

Sig. Half a dozen drops to be run into the affected ear after washing out and drying with a cotton-wool mop. Repeat the drops later in the day after mopping out only.

I do not wish to raise a controversy about the relative merits of the wet and the dry treatment. I find syringing in the hands of the school and child welfare nurses eminently practical so long as they have the encouragement of parents and teachers in the regular attendance of the child.

The ætiology of much chronic suppurative middle-ear disease is rather mysterious. We know how responsible are the acute infections and of the exanthemata Kerr Love gave first place to measles but some cases develop in a strange manner especially in the attic region and we have the problem of cholesteatoma. Childhood naturally provides the most useful period in which to study them.

I should like to say a little about those cases selected for operation though not all of attic type. What I call the "black" mastoid is often seen. The cortex being carefully removed we notice at once a dark reflex which suggests the proximity of the lateral sinus, but proves to be the first of a widely disposed system of cells filled with a mucoid-like substance and lined by a darkly stained membrane. I should like to know what happens to the mastoid system of such children who have avoided operation and perhaps disaster well into adult life. Might these cells be crowded out eventually by dense bone as far as the antrum?

In operations for attic disease we may find in children unsuspected cholesteatomatous deposits filling the cells right down to the tip of the mastoid process.

I should like to be better informed about the subject of cholesteatoma and the strange behaviour of the epithelium at the circumference of the tympanic ring.

Mr. J. F. Simpson exhibited some radon seed applicators which he had had made according to measurements provided by Major Fowler of the U.S. Air Force. These he had used in a very short series of cases. The small capsules, which he exhibited, unscrewed and took a radon seed (75 millicuries). Both were put in the nose at the same time, after spraying with cocaine. They were rested against the orifice of the Eustachian tube, the handles crossed at the anterior nares and tethered with a little piece of rubber band so as to bring them into contact with the Eustachian orifice. It was calculated that at a depth of 0·5 cm. from the wall of the capsule they would deliver a dose of the order of 750 r at each application. All these calculations had been made by the radiophysicist at St. Mary's. It was very necessary in all this work to have the help of a radiotherapist. When using radon seeds allowance must be made in calculating the time of application for the gradual decline in activity of the radiation. The usual dosage, if the seed was fresh, was twenty-two minutes. The capsules were left in situ both together for this period and four such daily applications in succession constituted a course. More than one course was sometimes necessary and if the case required it one could wait two or three weeks—preferably three—before beginning another course.

Mr. Simpson thought the treatment especially suitable for children in whom catarrhal deafness persists after removal of tonsils and adenoids and in whom politzerization gives only temporary improvement.

Mr. Gavin Young said that there were two main types of patients in this category. One consisted of the patients who suffered from nasal allergy; very often these were only children, and they did not appear to benefit at all, or benefited only very little, from removal of tonsils and adenoids. The other consisted of patients with chronic antral disease. It might be that in the damp west of Scotland they met more of these cases than in the drier regions of the south, but certainly a considerable number of cases did not clear up because of chronic antral disease, and he felt that rhinology had failed so far to deal adequately with this subject by failing to elucidate the pathogenesis of the condition.

Miss Winifred Hall said that her interest in these cases had been rather from the sociological than the clinical side. She described the working of school children's clinics where the responsibility for treatment was divided among several people, and stressed the need for these children to be dealt with as hospital cases, where all ear, nose and throat conditions could be treated by the same surgeon, who would also have full use of the hospital's radiological and other facilities.

Mr. F. C. W. Capps said that otologists who were called on to advise upon the disposal of these children should also carry out the operative treatment, at any rate all major operations, and should have facilities to follow these children up afterwards. He was asked, about 1934, by the Chief Medical Officer of the L.C.C. to make a survey of the aural treatment of children in London. He found the aural clinics very scattered, quite isolated from hospitals, and often in church halls and other unsuitable places. When operations were required they were sent away to a hospital outside London and operations were performed sometimes by men of very little experience in aural surgery. Some results were very bad. Much of this was in process of alteration when the war broke out, and the otologists running these clinics were being attached to a proper L.C.C. hospital with all facilities and ancillary services. Here they carried out the operations themselves, and all the necessary follow-up was done. This arrangement, which had given much improved results, broke down owing to the war, but he hoped that it would be revived.

As to chronic antral infection, or, perhaps not always "infection"—sometimes there was a chronic thickening of the lining of the mucosa of the antrum which led to improper ventilation or possibly improper insulation—he believed that in a large number of cases a routine X-ray picture of the sinuses was desirable. This need only be one view, to show the antra—the ethmoids were not so important as the antral cavity. He had found, too, that X-rays yielded valuable information upon nasal obstruction by adenoids. A true profile with soft tissue exposure was used.

He was prepared to confirm the President's impression that some of the cases of recurrent otitis media were hereditary.

Mr. R. G. Macbeth suggested that although it was admirable in theory that an otologist should be in ultimate charge of the investigation of these children, it was perhaps impossible in practice for him to see all of them. He wondered whether there was not a place in the scheme for the school medical officer with special experience, possibly the D.L.O., to act as a filtration bed. Many routine cases could thus be dealt with, and those requiring the otologist selected. It would be a tragedy if otologists were able to do less than their duty to those children most needing help, because they were expected to see very large numbers.

Mr. E. D. D. Davis said that he was in full agreement with the President, Mr. Capps and Miss Hall that all these cases should be examined thoroughly by an otologist in a properly equipped clinic. The patients should be examined again by the surgeon who undertakes any operation.

Mr. Francis McGuckin said that they were all grateful for the President's provocative Address on a wide subject. There should be no such entity as tonsils and adenoids to be contracted out by local authorities. The otologist should have the review of the whole child, accompanied by a parent, preferably the mother. Too little note was taken of the historical contribution which could be made by the home doctor. It was time that the local authorities realized that the consultation and observation were just as important as—probably more important than—operative work. As far as was practicable, decisions should be taken by the surgeon who was to operate. His own preference would be that these services should form part of the hospital service rather than remain an isolated unit.

Some criticism of the term "catarrhal otitis" might be advantageous. There were several groups: (*a*) the accident of an acute otitis chiefly bacterial in type; (*b*) repeated acute otitis of varying severity, unilateral or bilateral, with satisfactory healing between attacks; (*c*) the otitic lesion which was chronic from the start; (*d*) recurrent negative pressure syndrome characterized by in-driven drum and a little retention fluid in the middle ear. In these cases the fluid was almost certainly not inflammatory and it was possible that it was no more than an accumulation of mucus not eliminated via the obstructed tube. A further group (*e*) was the permanent perforation syndrome with loss of protection from without and the failure of the air piston from within. In these cases the bigger the perforation the more frequent the otorrhœa, but the safer the nuisance.

In some of the aforesaid groups the mechanics and pathology were understood fairly well, but in others less well. Did the term "catarrhal otitis" really describe any definite group either in relation to pathology or simple mechanics? Did it cover a reasonable entity either in respect of the ear or the upper respiratory tract? Tonsils had little or no direct effect upon the ear, though acute diffuse infection involving the tonsils might spread to the ear, and anything producing great swelling of the palate might occlude the tube. The role of adenoids was fairly obvious.

He believed it was just as unscientific to hold the entity of Eustachian obstruction as of bile-duct or urethral obstruction, without regard to the specific mechanical cause. In the past he had said that he knew of four definite causes, and he was still seeking for more. These causes were (1) trauma, which might arise from unskilled surgery with damage to the torus and possibly from a fracture involving the muscular relations of the Eustachian tube (barotrauma with flutter valve obstruction might also be included); (2) neoplasms, simple or malignant; (3) œdema of the torus, secondary to inflamed lymphoid tissue attached perhaps to the posterior limb of the torus or secondary to a flow of pus over the cushion, e.g. antral suppuration with a deep uncinate gutter or a sphenoidal suppuration (in these cases the rounded tubal entry could be seen to be reduced to a mere slit); (4) adenoids, in which case the usual obstruction arose from the mere covering of the tubal torus by the adenoid tissue, but he had already mentioned another possibility. The obstruction might be an uncomplicated mechanical thing or, if the cause be infective, then the aural result might be a mixture of inefficient air exchange plus bacterial complication.

There was no time to cover adequately the ætiology of chronic otitis, but he did hold the view that many cases—perhaps a considerable proportion—were chronic from the start, and he believed it was time the Section had a further full-scale discussion on cholesteatoma, which might include keratosis and aural dermoid. It had been his ambition, as yet unfulfilled, to have all the infantile ears in three hospitals in Newcastle observed and noted each day. He believed that in this way they might learn a great deal about the possibilities of congenital attic cholesteatoma and perhaps of primary pseudocholesteatoma. They had still to solve the problem of the acute ear which was smelly from the start and also of the extensive damage which might be quite unadvertised in the presence of a sterile cholesteatoma.

The President had coined the epigram "Squamous epithelium lies uneasily upon bone". That he fully agreed with, but it might also be added that keratinizing squamous epithelium might lie quite easily in the middle-ear cleft until such time as an accident occurred. Nothing more than moisture was required to turn this innocent condition into something threatening and destructive. The accident might be a common cold with a mild otitis, a visit to the swimming baths, or some other slight incident, but he thought they must admit that many of these cases were rendered active by the mere use of an ear syringe or the instillation of ear drops.

The President had asked for information about radiotherapy in the post-nasal space. The speaker had tried this on a few occasions where other therapy seemed unsuitable. The numbers were insufficient to draw any conclusions, but he was prepared to be disappointed.

Mr. A. S. H. Walford said that from experience around Cambridge he did not think there was any difference in the incidence of adenoids as between children from town or country. The condition had nothing to do with environment. The ordinary country population certainly had just as much adenoids as the town. There was also a considerable proportion of these children who were really suffering from antral infection rather than infected tonsils and adenoids.

Section of Radiology

President—WHATELEY DAVIDSON, M.D., F.R.C.P., F.F.R.

[*November* 15, 1945]

DISCUSSION: THE X-RAY TREATMENT OF INFLAMMATORY DISEASES

Dr. Mary Cripps: *The effect of X-radiation on the eye from its clinical aspects.*—Following the successful treatment by X-radiation of herpes ophthalmicus in 30 cases, I tried it on other conditions. I found that it had a definite usefulness in certain categories of ophthalmic cases but that its sphere was limited. Briefly, the application of X-radiation (where the intra-ocular tension[1] is normal or subnormal) to minor lesions yielded good results within three to seven days. If, on the other hand, the inflammatory condition from injury or otherwise was severe and the tension on an average above normal, a larger dose and a longer time were required. The aggregate effect of X-radiations on ocular tissue in my experience raised intra-ocular tension for a period too long to give satisfactory results from the point of view of visual acuity. For instance, a case of cataract extraction suddenly developed an infarct of lung, accompanied by vomiting and followed by opening of the extraction wound. X-radiation healed the wound with a temporary increase of intra-ocular tension which lasted for a period of almost two years and then returned to normal, a period of raised tension too long for the preservation of useful vision, but which may point to the ability of X-radiation to upset the vascular equilibrium for this period. The return to normal of the raised tension showed that the eye had been through a period of unstable equilibrium after X-radiation.

Therefore, I was forced to the conclusion that X-radiation for the successful treatment of ocular lesions must be confined to the category of cases where the intra-ocular tension was not raised and the lesions minor (16 cases). But when

---

[1] Intra-ocular tension: *Normal tension*—On an average 33 mm.Hg Schiotz Tonometer, without weights; *Subnormal tension*—On an average *below* 33 mm.Hg Schiotz Tonometer, without weights.

More could be done to prevent catarrhal infections in school children. The young child during his first term at school lost three-quarters of it through bad colds. Such a child is a carrier and should not go to school during a cold, but the mother complains that in that event the child lost his dinner and his free milk. He thought there should be some form of isolation. If a roll is called any child who showed signs of a cold should be inspected, and, if the temperature was above 99° he should be sent home or isolated with other similar children.

The ventilation was important. It is stated that the temperature of the schoolroom should not be above 65°. A temperature above 65° meant that the ventilation was inadequate.

He had seen cases treated by radium and deep X-ray therapy in which burns had occurred and the mucosa never recovered its normal condition. Serious damage had been done without any benefit to the patient. He advised every otologist to be guided by a skilled radiotherapist.

Mr. R. Scott Stevenson said that as we knew very little about the remote results of radium in the tissues of children it was to be hoped that it would not be used indiscriminately nor without careful supervision by an expert on radiotherapy.

Mr. W. A. Mill emphasized the dangers of unregulated radium treatment.

Mr. A. M. Ross said that one point to which attention should be drawn was that general practitioners and the public were still not sufficiently alive to the dangers of ear trouble in children. The dangers tended now to be further masked by the tendency to give the sulphonamide drugs for earache without much discrimination.

Dr. J. Alison Glover said that the latest figures for public elementary school children in London for the incidence of running ears was 0·5%; the figure was some 9 times that when he first entered medicine, and all otologists were to be felicitated on so great a reduction. He was heartily in sympathy with those who had spoken about home conditions. These—and, of course, school conditions also—were most important factors in otitis. Perhaps school hygienic conditions were not quite so important as home conditions, but they were extremely important, and every improvement in school buildings and in the home was to be welcomed. Fortunately, the overcrowding necessitated by war conditions did not seem much to have affected the picture. For some reason or other the incidence of otitis, the mortality from rheumatic fever, and the incidence of the other streptococcal complications after measles and scarlet fever had all been going down recently.

Asked by a member whether it would help matters at all if otitis were to become a notifiable disease Dr. Glover said that he would rather doubt whether formal compulsory notification would be helpful.

The President, in replying, said that the question of "acute or chronic otitis" in relation to the origin of chronic middle-ear suppuration, led one to inquire into the difficult problem of how cholesteatoma originated.

Mr. Simpson had shown how the "cross-legged" method recommended by Fowler was used for his radon applicators so that the applicators would remain closely applied to the region of the Eustachian orifices. He himself had feared to use radiation in any form. After all, the pituitary was not very far away and though it was true it was shielded by bone, it was the key gland of the endocrine system and serious consequences might follow if it were disturbed.

Mr. Davis had suggested that the otologist was worthy of his hire. Those in authority could not neglect the problem of the prevention of deafness and that of the complications attendant on middle-ear suppuration. The otologist must also perform a certain number of operations on the lymphadenoid tissue of the throat.

Mr. Scott Stevenson also had uttered a warning about the use of radiation. Among other points raised was the general practitioner's over-use of the sulpha drugs, but nevertheless he would rely on the judgment and wide experience of the general practitioner in their administration, though warn him of cases of persistent deafness and latent mastoiditis which sometimes followed the abatement of acute symptoms.

Healing.—X-radiation promotes and accelerates the process of healing. It exerts its influence not only superficially but to a great depth. This property adds to its value in the healing of deep penetrating wounds.

Blood-counts taken before radiation and which show an increase in mononuclear leucocytes as a result of a specific inflammatory lesion show that, after radiation, as the inflammation subsides, there is a reduction in number, and a return to normal of these cells. An especially persisting increase arouses suspicion of involvement of the uninjured eye by sympathetic ophthalmia as a complication of deep penetrating wounds.

Fibrin grafts when applied to gaping wounds of the sclera appear to irritate the eye at first but after X-radiation the eye gradually settles down and excellent results follow. The graft eventually is indistinguishable from the surrounding sclera.

Speaking generally eyes with normal or subnormal intra-ocular tension derived most benefit from X-radiation. *Minor* lesions recovered completely in a short period of time, about three to seven days. Cases of greater severity required a longer time to recover and were apt to be disappointing except where intra-ocular tension was subnormal. Eyes showing increased intra-ocular tension accompanied by pain from mechanical causes, e.g. glaucoma, do not derive much benefit from X-rays. The properties of X-rays associated with their action in depth prevent or abort sympathetic ophthalmia in the uninjured eye.

CONCLUSIONS

X-radiation for the successful treatment of ocular lesions must be confined to the category of cases where the intra-ocular tension is not raised and the lesions are of a minor character. When X-radiation was combined with ultra-short-wave diathermy satisfactory results were obtained (198 cases). Lesions healed with a minimum of scar tissue, intra-ocular tension remained normal and the maximum amount of visual acuity was obtained. Further there were no clinical signs of the disturbance of vascular equilibrium.

Dr. Alfreda H. Baker: *X-ray treatment of osteomyelitis of the fingers.*—One of the most troublesome complications of a septic finger is a persistent subacute or chronic osteomyelitis of one or more phalanges or of the metacarpus. The patient may be disabled for weeks or even for months after the acute inflammation has subsided by a persistent discharging sinus and by pain and tenderness of the finger. Permanent disability is not rare, and, if the digit involved is the thumb or index finger, loss of occupation may result. If, on the other hand, sound healing of the bone can be secured, the prospect of obtaining a useful finger is greatly increased. Too often, in an effort to cut short the infective process, the patient is subjected to several operations at which fragments of bone are removed under the misapprehension that they are sequestra and that their presence is delaying healing. Sequestra do form in some cases, and the loss of bone seriously deforms the affected finger. More often the friable, but living, decalcified bone breaks up under the persuasion of a metal instrument and fragments are pulled out. Even without the aid of X-ray therapy the bone may recalcify if left alone. Every experienced casualty officer learns in time the value of conservative treatment. The process may, however, be long and tedious, and the impatience of doctor and patient may suggest amputation as the quickest way to end the pain and to get the patient back to work. A method that is likely to promote complete healing and functional recovery in a matter of weeks is obviously worthy of attention. Such a method is combined with ultra-short-wave diathermy I obtained satisfactory results (198 cases). The equilibrium remained stable and the intra-ocular tension normal and there were no unsatisfactory sequelæ.

Technique and dose.—The apparatus used in treatment was the superficial X-ray therapy unit with a Victor's tube 100 kV. 1 mm. Al. inherent filter equivalent 5 mA. 27 cm. focal skin distance. *Dose*: The doses used by Dr. Dalton and later by Dr. Woodham of the Ipswich and E. Suffolk General Hospital are as mentioned hereafter. All are expressed as surface/r. Time taken to deliver 100 s/r 1 min., 18 sec.; 50 s/r 39 sec.

Dividing the cases according to ophthalmological signs and symptoms into acute inflammatory (or traumatic) cases, and chronic cases, the optimum dose used for the acute variety was 200 to 225 r given as 100:50:50 r *or* 75:75:75 r. The interval elapsing between each exposure was three to six days. The whole treatment was given within ten to fourteen days.

Ophthalmologically chronic cases.—These reacted better to smaller doses, so the optimum total employed was 125 to 175 r spread over three weeks, as follows: 50:50:25 r *or* 75:50:50 r. The interval allowed between each exposure averaged seven to ten days, the whole treatment having been given in three weeks.

Action.—Evidence of reaction to X-radiation may be deduced from the hyperæmia of the ocular tissues. Whether the value of X-ray depends on the direct effect of radiation on the pathological cell which is more sensitive than the normal one, or whether it is due to the stimulating action it exerts on the neighbouring tissue is not determined. Probably all these various factors operate together but each with varying intensity in individual instances.

The effect on ocular tissues.—The conjunctiva is the most sensitive of all the ocular tissues to X-radiation. The lens appears fairly resistant but when exposed to too heavy radiations may become cataractous. Corneal ulceration and interstitial keratitis have been described after prolonged exposure to X-rays. The retina offers a fair degree of resistance. The action of X-rays on vitreous which has prolapsed is interesting. After X-radiation the vitreous appears to become almost imperceptibly more viscous. This has been observed within six hours of a single dose to the eye of 100 s/r.

After this initial stage of greater viscosity the prolapsed vitreous begins to retract into the globe, and in about forty-eight hours the process of retraction is very nearly completed. What is of value and interest is that the vitreous remains clear without any perceptible abnormality, giving maximum vision; the period of observation is five years.

Effect on ocular signs and symptoms.—Symptoms characteristic of ocular irritation—lacrimation, photophobia and pain—need further mention. X-rays relieve pain as in herpes ophthalmicus where it is of nerve origin; pain produced by mechanical causes, such as we find in glaucoma, is not helped to any appreciable extent.

Intra-ocular tension.—The summation effect of X-rays is apt to raise intra-ocular tension for no discernible reason. It is well to use the intra-ocular tension as a "control" whenever diathermy is applied.

Injection of uveal tract.—X-radiation quietens the irritable eye. Purple injection of the uveal tract fades away gradually and the eye regains its normal appearance.

out only by an experienced radiologist, as an excess dose might fail to produce the desired effect, or might even delay healing.

Summary of the results.—In a small series of cases the results were uniformly successful. They were better when we had the cases early, for then we could be sure of preventing loss of bone by sequestrum formation. In at least three cases an apparently inevitable amputation was avoided. The sinuses healed, the evidence of inflammation of the soft parts disappeared, and the patients lost all fear of using the affected digit.

At the same time, and in a matter of weeks, the appearances of the radiographs quite changed. The ghost-like bone recalcified, and its pattern reappeared. Destruction of the joint surfaces and loss of bone substance were the two factors that gave rise to permanent radiographic changes.

The conclusion from clinical observation is that X-rays did something that neither local nor general antibacterial therapy was able to accomplish.

Dr. Francis Freund: *Action of X-rays on inflammation.*—The main reason for the healthy scepticism about this treatment is that the mode of action is unknown. Any explanation should correlate the histology of the normal course of inflammation with the histology of the changes caused by X-rays. The whole conception about inflammatory reaction has changed fundamentally in the last twenty years.

In recent editions of textbooks on pathology it is stated, that in acute and chronic inflammations local cellular reaction plays the major part, and emigration of cells from the vessels a minor part. The cells of the vessel walls, the adventitia cells, the cells of the reticulo-endothelium and even of the alveolar epithelium of the lungs, in short all cells of mesenchymal origin, can change into inflammatory cells. When healing takes place the mononuclear inflammatory cells change back again into fibrocytes and fibrous tissue. The polymorphonuclear inflammatory cells disintegrate and are not capable of differentiation. Cells of mesenchymal origin regain the faculty of differentiation in post-embryonic life under the following conditions: (1) Myelosis, (2) Inflammations, (3) Callus formation.

It is an obvious conclusion that X-rays might influence this differentiation. Before going into the study of the action on cells, the action on bacteria should be discussed.

No action on bacteria has been described when a small dose of X-rays is applied. Dr. Cadness-Graves and I have recently experimented on bacteria of all sorts and under varied conditions, and we could not find any definite evidence of a loss of vitality of the bacteria. One would expect that an increase and not decrease of the dose would be more beneficial if bacteria were affected and, in addition, aseptic inflammations respond equally well to the treatment. It is therefore justifiable to state that the action of X-rays on inflammations is not bactericidal.

I inflicted small wounds in the centre of the cornea of animals under local anæsthesia. Rapid healing occurred compared with controls. As there are no vessels in the centre of the cornea the healing effect cannot therefore be attributed to an action on blood-vessels, as some authors assume. Having eliminated the possibility of any effect on bacteria and vessels, we can turn now to the action on tissue cells.

Action on polymorphonuclear leucocytes.—It is widely believed that destruction of polymorphonuclear leucocytes is responsible for the healing effects. That these provided by a simple application of the principles of the effect of X-rays on inflammatory processes. Experimental work carried out by Freund in 1929 (*Strahlentherapie*, **33**, 375) and by Fukase, 1929 (*Virchow's Arch.*, **273**, 794) has shown that X-rays had a beneficial effect on the recovery from inflammatory lesions. These observers investigated the behaviour of mesenchymatous tissues under the influence of X-rays, and their conclusions were that the differentiation of inflammatory cells into fibroblasts and fibrocytes was stimulated. In bone lesions they demonstrated that re-ossification was promoted in conditions characterized by deficient bone formation. Dr. Finzi and Dr. Phillips started X-ray treatment of osteomyelitis of the fingers at St. Bartholomew's Hospital in 1939. The radiographs of a case treated by them (*Brit. med. J.*, 1943 (i), 34) show extensive destruction of bone and complete regeneration in a case in which the question of amputation had been seriously considered. The dose used was 30 to 80 r, and 160 kV. filtered with 0·5 mm. of copper.

We wished to use this treatment for patients of the Emergency Hospital at Oster House, St. Albans, but we were unwilling to send the patients to London during the worst period of the flying and rocket-bomb attacks, and Dr. Freund suggested that we should use the diagnostic X-ray plant of the hospital. The radiographs [*shown*] demonstrate the results obtained by this simple method (*see* figs. 1 and 2).

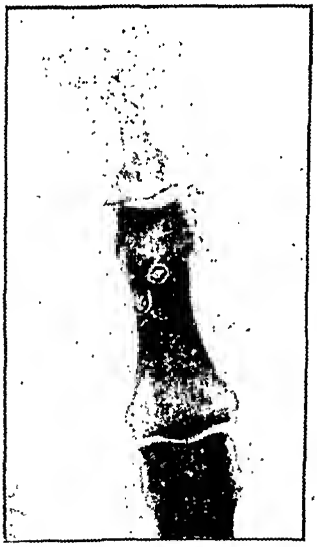

FIG. 1.—N. H. Osteomyelitis of four weeks' duration. Organism: *Staphylococcus fluorescens*. Daily irrigation with penicillin without success.

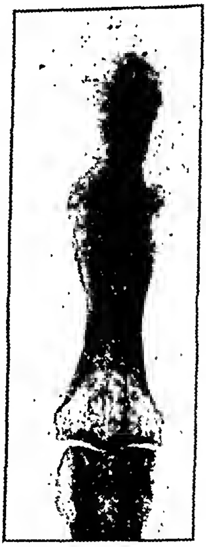

FIG. 2.—After screening with the diagnostic tube in the normal screening distance, 60kV./3ma. three minutes weekly, for five weeks.

The septic digits were screened, using the screening voltage of routine fluoroscopy at the usual screening distance. The dose required was calculated as one-tenth of the erythema dose. Twenty minutes' exposure with the diagnostic apparatus under ordinary screen conditions was taken as being an erythema dose, and two to three minutes as a suitable dose for our purpose. This dose (50 to 75 r) was given once a week for three to five weeks. Being only one-tenth of the erythema dose it could not inflict burns. Nevertheless, Dr. Freund insists that the treatment should be carried common occurrence of delayed repair. *Small doses of X-rays initiate repair or prevent exuberant local reaction by their differentiating effect upon inflammatory cells.* Under the assumption that bacteria or leucocytes should be destroyed, too high and too many doses are given. Differentiation takes time and requires not more than 50 r, once a week. The treatment of osteomyelitis and of inflammatory conditions of the eye are only easily demonstrable examples of the general principle involved. The clear conception of what we are doing makes the enumeration of indications superfluous and leaves it to reason. Even less apparent inflammations are excellent indications for X-ray therapy. If, for instance, skin grafts are not readily taken, a small dose of X-rays checks the unwanted local reaction, and almost invisible scars can be achieved.

Here again we have only another example of the power of X-rays to exercise control, rather than to destroy.

Dr. N. S. Finzi: During most of my earlier radiological career, I was trying for many years to persuade radiologists to give sufficient dosage in malignant disease in order to attempt to cure, and not merely to palliate. Having eventually succeeded in this, I am now having equal difficulty in trying to persuade them to give small enough doses in inflammatory conditions. I first realized this at the International Congress in Stockholm in 1928, when a report was presented showing better results in tuberculosis with smaller than with larger doses. Since then my results, both in tuberculosis and other inflammatory conditions, have very definitely improved as the result of the use of smaller dosage. I admit that successful results can very often be obtained with medium dosage, but they are not so good or so frequent as with small dosage, and the length of time over which the treatment can be spread is very much less. On the whole, the dosage to be aimed at is 50 to 60 r lesion dose, with penetrating rays, as a start, gradually decreasing to about 40 r once every five to seven days. With less penetration, smaller doses must be given. As an instance, when Mr. Ralph Phillips first started treating osteomyelitis of the finger with X-rays, he used 100 r twice a week. When I persuaded him to use 50 r every five to seven days, the results were not only as good, but better.

One extraordinary feature which one observes in these osteomyelitis cases is the disappearance of sequestra. What any radio-diagnostician would be quite certain is a sequestrum will very often become incorporated in the new bone, with no evidence, either radiologically or clinically, of the persistence of a sequestrum.

I want, in particular, to draw attention to the treatment of arthritis with these smaller doses. One must, of course, remember that there is always much more absorption of the rays by bone than is given in any dosage curves. It amounts to 15 or 16% extra when using 200 kV. and a Thoraeus filter, and is correspondingly greater when using rays of less penetration. I find that, when this is taken into consideration, and the dose regulated accordingly, the results obtained in some of these cases are very striking. But I also use an adjuvant, which is not known to cells are destroyed is based on investigations which Warthin carried out in 1905. He tried to prove that the disappearance of leucocytes in the blood-stream of leukæmic patients is due to destruction of leucocytes by the direct action of the rays. This very plausible explanation is *not* borne out by facts. In exudates which I produced experimentally in the dorsal lymph-pouch of frogs, an increased disintegration of polymorphonuclear leucocytes can be observed after irradiation. I never attached much significance to these changes, because disintegration of polymorphs takes place in any exudate and only speeding up of a breakdown into pus might be explained.

I had the rare opportunity to treat a patient with myeloid leukæmia who had numerous myeloid nodules in the skin. In a biopsy made before and after treatment the differentiation of cells of mesenchymal origin into mononuclear leucocytes can be clearly shown. After irradiation the change into fibrocytes and fibrous tissue can be seen. There is no evidence of young fibroblasts, but the actual cells have changed, the nucleus has become dense and stretched and layers of fibrous tissue surround the nucleus like onion skins.

We know that spontaneous healing of such myeloid nodules does not occur. The cure has been achieved by the differentiating action of the X-rays. It is a reasonable step to assume that under inflammatory conditions mononuclear leucocytes might likewise change into fibrocytes and fibrous tissues.

Action upon mononuclear leucocytes.—I studied the normal course of inflammation in the frog's tongue, an experiment recommended by Cohnheim.

The slides showed widespread cellular activity going on outside the vessels, before any emigration from the vessels had occurred. The fragmentation of the nucleus and the formation of polymorphs in the early stage of inflammation could be demonstrated.

After these findings I thought that the local growth of inflammatory cells might be prevented by prophylactic X-ray treatment and rapid repair achieved. Wounds inflicted on the skin of rabbits healed quicker in the irradiated part. The histological slides confirm the macroscopic appearances. There is an exudate in the part not irradiated, there is no inflammatory reaction in the irradiated one.

In order to exclude infection and to have an object that can be easily demonstrated, the traumatic inflammation after fracture was studied before and after irradiation. The fibula of rabbits was fractured on both sides. On the irradiated side the callus formation was less, but firm bony union occurred earlier. The histological slides show, after five days, mononuclear granulation tissue, but fibrocytes on the irradiated side. After eight days you see cartilage cells appear, if not irradiated, and fibrocytes and fibrous tissue, if irradiated. The dose was 400 r; if the dose is increased to 1,600 r, delayed union takes place. The fibrocytes assume the character of embryonic mesenchymal cells and after three weeks the differentiation into numerous capillaries takes place, preventing bony union for several weeks. Even a dose of 400 r shows changes of the fibrous tissues, specific of X-ray irradiation. It serves as a warning to give very small doses in order to avoid damage to defence and repair.

DISCUSSION AND CONCLUSION

The rationale of the osteomyelitis treatment, discussed by Miss Baker, can be explained by the experiments shown. Debris, devitalized tissues, constitutional and nutritional causes often delay repair, long after the danger of general infection has passed. We can visualize delayed bony union, but this is only part of the

Clinical Section

President—A. DICKSON WRIGHT, M.S., F.R.C.S.

[*November* 8, 1946]

Myelosclerosis with Leukæmoid Blood Picture.—E. IDRIS JONES, M.D.

Male, aged 51. Plumber for thirty years, store-keeper for last eight years. Admitted to hospital September 1942 because of increasing pallor and loss of energy for previous six months. No other symptoms.

On examination.—Pallor, spleen enlarged 2½ in. below costal margin and liver 2 in. down. Slight enlargement of inguinal glands, rest normal. B.P. 122/70. Heart, lungs, C.N.S.—N.A.D.

Blood-count (18.11.42).—R.B.C. 3,140,000; Hb. 54%; W.B.C. 8,700 per c.mm. 5% reticulocytes. Polys. 68%, eosinos 1%, lymphos. 22%, monos. 2%, premyelocytes 4%, myelocytes 3%. 15 normoblasts per 100 white cells.

Radiography of bones showed dense sclerosis, especially at base of skull. Sternal marrow not obtained by puncture so sternum was trephined and sections made of bone. These showed increased trabeculation with increase in collagen fibres and scanty islands of bone-marrow with little or no fat.

Anæmia did not respond to treatment, splenomegaly increased but blood picture remained approximately as above until June 1946. Increase in immature white cells then occurred and patient has developed dyspnœa and œdema of legs. Spleen now well below umbilicus with systolic murmur audible over it.

Blood-counts:

3.6.46: R.B.C. 2,600,000; Hb. 50%; W.B.C. 33,200. Immature red and white cells present.

9.9.46: R.B.C. 3,140,000; Hb. 50%; W.B.C. 54,700. 30% immature white cells and 14 immature red cells per 100 white cells.

4.11.46: R.B.C. 2,750,000; Hb. 40%; W.B.C. 82,000. Polys. 45%, basos. 6%, monos. 3%, premonocytes 4%, lymphos. 3·5%, metamyelocytes 12%, myelocytes every radiologist. This is the application, in the case of the upper limb, of X-rays to the lower cervical and upper dorsal region; and, in the case of the lower limb, to the lumbosacral region, aiming again at a similar lesion dose. I discovered this by accident when treating a patient with X-rays for a stiff neck. She had had for many years very bad arthritis of the hands. As a result of treating the neck, the hands improved so much without any direct treatment that they were better than they had been for twenty years. I discovered later on that the treatment was not new, as it had been used in America three years before, but I have unfortunately forgotten the name of the investigator who published the work.

We got excellent results at St. Bartholomew's Hospital in cases of spondylitis ankylopoietica by using a dose of 75 r at 60 or 70 cm. F.S.D. on the surface, which meant a dose of 50 r at the lesion, and repeating this every five days. There may be cases which require higher dosage, but most of them will respond to this smaller dosage.

While on the subject of arthritis, I must mention the results in sciatica and other forms of neuritis, including the post-herpetic variety and also the results in fibrositis. In sciatica there is often a tender spot at a certain point in the buttock, and if this exists, the case can nearly always be cured.

Another condition where I have treated a number of cases with smaller doses is mastitis, my most striking case being one in which the lumps were so large that both the surgeon and I felt that one breast must be removed to make sure that our diagnosis was correct. When this had been done, I treated the other breast and the lumps completely disappeared and she remained cured for many years.

In view of the low dosage employed, the treatment can be continued over very long periods if necessary, without any danger of permanent damage to the skin or subcutaneous tissues.

Conclusion.—A case of primary xanthomatosis with biliary cirrhosis.

Dr. F. Parkes Weber agreed that the case was a perfect example of tuberous (elbows and knees) and plane (hand creases) xanthomata of Thannhauser and Magendantz's hypercholesterolæmic group of primary essential xanthomatosis (as described by them in 1938) with jaundice due to xanthomatous biliary cirrhosis. In a booklet on "Cutaneous Xanthoma and Xanthomatosis of Other Parts of the Body" (1924, p. 10) Dr. Weber referred to a number of cases of xanthomatous biliary cirrhosis, but failed to recognize that they formed an important part of the group afterwards (1938) distinguished by Thannhauser and Magendantz as their hypercholesterolæmic group.

Sarcoma of Bronchus.—IVOR LEWIS, M.S.

C. C. H., aged 14, was admitted to the North Middlesex Hospital on June 23, 1946, complaining of shortness of breath for three months, with some pain in the right chest, some cough, a little phlegm but no hæmoptysis. The day before admission he became much more breathless; previous history of occasional bronchitis, nothing suggestive of aspiring a foreign body.

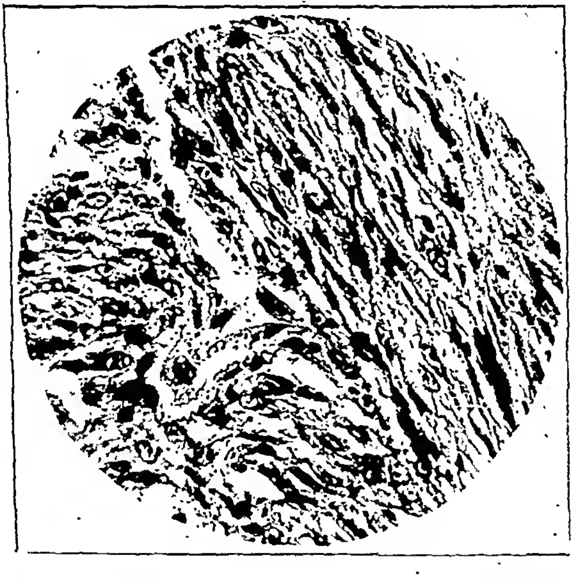

FIG. 1.—Biopsy, October 10, 1946. The section shows well-defined fibroblasts cut in several planes. In this instance the cells on the average are more protoplasmic than in the second biopsy. Masson's trichrome stain. × 400.

On examination.—A pale, very tall boy (5 ft. 10 in.), moderately breathless and a little blue; T.101, P.120. There is no clubbing, trachea and heart greatly displaced to the right, dull, right base. A little sterile, straw-coloured fluid was obtained from the pleura. X-ray at this time (June 25) showed widening of the mediastinum with much displacement of heart to the right. His pyrexia disappeared.

July 9: X-ray—the right upper lung now entirely opaque except for a small area of the R. upper lobe, with the heart completely to the right of midline.

21·5%, premyelocytes 2%, myeloblasts 3%. 7 normoblasts, 4 erythroblasts and 1 megaloblast per 100 white cells.

Blood uric acid 2·9 mg.%.

Total plasma protein 6·8 grammes%. Albumin 3·3 grammes. Globulin 3·2 grammes. Fibrinogen 0·3 gramme.

Dr. F. Parkes Weber remarked that in such cases the question arose: (1) Is the leukæmoid blood picture secondary to the myelosclerosis, or (2) does the myelosclerosis represent a bone-reaction which may be explained teleologically as an attempt to oppose a leukæmic expansion of the bone-marrow? In the present case it seems more probable that the leukæmoid blood picture represents a regenerative reaction towards the damage done by the myelosclerosis to the hæmopoietic organ (the bone-marrow).

Dr. Weber thought that X-ray examination in the present case shows that the myelosclerosis is only part of a general osteosclerotic change of the nature of osteopetrosis, that is to say, "marble bones." The case is not unlike Albers-Schönberg's original case (1904) of "marble bones", though the bone changes are less. The patient in that case was not a child, as in many cases of "marble bones", but was an adult man, who died in 1927 in his 49th year, and whose case was afterwards fully described by F. Reiche, 1929 (*Münch. med. Wschr.*, 76, 1078).

Xanthomatosis.—C. P. PETCH, M.B., M.R.C.P. (for Professor de WESSELOW, D.M., F.R.C.P.).

A woman of 55 complained that for thirteen months she had suffered from discoloured areas of the medial portions of the upper and lower eyelids on both sides. These were treated a year ago by cauterization and it was noted at that time that she was slightly jaundiced and had a large liver. Since then the discoloured areas have increased in size and similar patches have appeared on both elbows and both knees. The palmar creases are also the site of the yellow deposits.

The jaundice has increased slowly. She has had no other symptoms and her previous health has been consistently good, apart from hysterectomy for fibroids in 1937.

On examination.—Marked jaundice with heavy xanthomatous deposits in the areas previously described and on the great toes. The liver is enlarged about 5 in. below the costal margin and is hard and smooth. The spleen is palpable. There is no abnormality in the C.V.S. Blood-pressure 145/85. The urine is normal.

Investigations.—X-rays of chest, skull and lumbar vertebræ show no abnormality, apart from small areas of patchy sclerosis in the cranial vault. No calculi in gall-bladder region. E.C.G. shows no significant abnormality.

Blood: Hb. 84%; W.B.C. 5,600. Polys. 69%, lymphs. 26%, eosinos. 1%, basos. 1%, pathological lymphos. 2%. Van den Bergh reaction direct positive. Fasting blood sugar 95 mg.%. Normal glucose tolerance curve.

Plasma proteins 8·88%—albumin 3·75%; globulin 5·31%.

Plasma lipids—mgm. per 100 c.c.

Non-phospholipid fatty acids	452	Free cholesterol	311
Neutral fats	226	Estercholesterol	328
Phospholipids	743	Total cholesterol	639

Liver function by the hippuric acid test was 110% of normal.

Prothrombin time 19 seconds.

Urinary urobilinogen 1·8 mg. per 100 c.c.

Fæcal urobilinogen 120 mg. per 100 c.c.

in Von Reckinghausen's disease. Sections prepared from several parts of the tumours of the stomach showed that these possessed a different and unusual structure. These tumours were composed of epithelial cells, small in size, oval or spheroidal in shape. The nuclei were round or oval, and the cytoplasm scanty and sometimes vacuolated. Special stains for fat, mucin, and glycogen gave negative results. An occasional small mononucleated giant-cell was seen. Rosettes were not found. The cells were separated by an abundant intercellular substance, which by special staining was seen to contain a reticulum, in which the cells were disposed in fascicular fashion. It is thought that the tumours are neuro-epitheliomatous in structure and are composed of neuro-ectodermal cells displaced during development with the peripheral nerves (fig. 2).

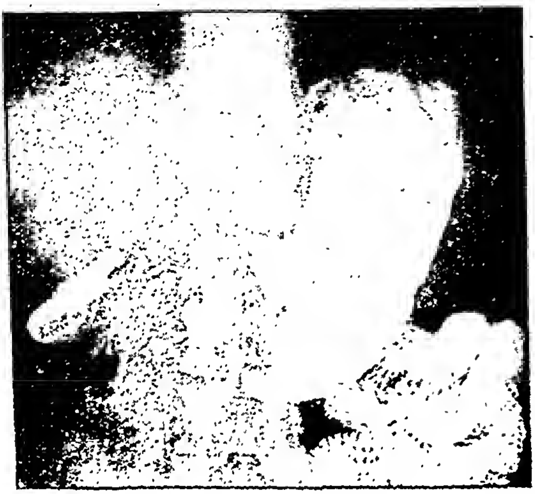

FIG. 1.

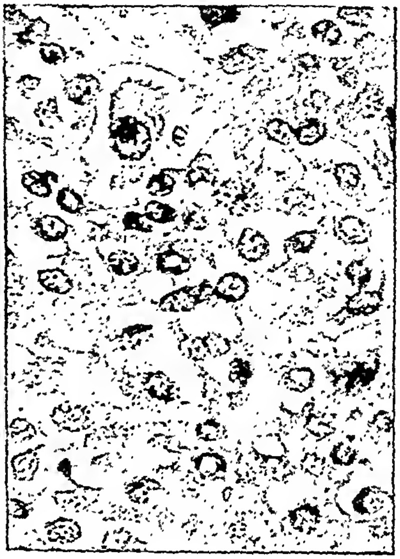

FIG. 2.

FIG. 1.—Stomach, prone, showing circular filling defects in antrum.

FIG. 2.—Photomicrograph of representative part of tumour of stomach showing the characteristic cells. ×430.

Cirsoid Aneurysm.—K. W. PRIDDIS, F.R.C.S. (for Mr. ALAN SMALL).

E. P., female, aged 17½. Clerk.

History.—January 1945: She presented at Tilbury Hospital complaining of inequality in the size of her legs. Apart from this she experienced no subjective symptoms nor incapacity.

June 1945: She fell downstairs and bruised her right knee. She was admitted to London Hospital where after a week in bed an ulcer developed 1 in. below the right patella. It has been present ever since. While still in hospital at rest she suffered three secondary hæmorrhages, the last one being massive. It was controlled by digital compression of the femoral artery and later by a firm pressure

July 18.—Bronchoscopy (I. L.) showed the orifice of the R. bronchus to be filled by a soft, yellowish white growth, a little firmer than brain tissue. Only a small chink remained open. The attachment of the growth extended right up to the carina. It was not lobulated. Large pieces of it were removed by forceps, securing good entry into the bronchus; a fair amount of bleeding.

X-ray next day already showed re-aeration of about half the R. lung.

August 7 to 29: Course of radiotherapy, Total 6,353 r.

August 10: Re-bronchoscoped. There was now a smooth prominence, rather like an inflamed turbinate viewed from the posterior nares.

September 3: X-ray showed normal position of heart with practically complete aeration of the R. lung.

October 10: Bronchoscopy; only a small residual growth, 1 cm. long × 2 mm. × 2 mm. arising from the posterior wall of the bronchus at its junction with the trachea.

Biopsy.—July 18, 1946 (Mr. T. H. C. Benians): "Growth is made up of spindle cells widely separated by œdema and arranged in whorls. Considerable variation of the nuclei. I think the tumour should be considered a fibrosarcoma."

October 10, 1946 (Dr. J. F. Heggie): "Still shows a cellular growth composed of spindle cells arranged in irregular bundles. They appear more protoplasmic and more actively growing than previously. Despite the relative absence of mitotic figures the condition is sarcomatous."

Neurofibroma of Stomach in Von Recklinghausen's Disease.—T. W. MIMPRISS, M.S.

Male, aged 68.

Family history.—Grandfather, father and daughter have neurofibromatosis. Patient shows cutaneous manifestations of this condition very well, otherwise has been fit.

Previous history.—Indigestion and epigastric pain for eighteen months, with flatulence and vomiting. Has lost 1½ st. in weight.

On examination.—Large abdominal tumour, 4 in. in diameter, moving on respiration, palpable at level of umbilicus.

Barium meal showed filling defect of stomach suggesting large polypus (fig. 1).

In view of his general condition tumour was diagnosed as neurofibroma.

Test meal showed no free HCl, lactic acid present.

At operation the tumour was found to be growing from the greater curvature of the stomach. The large part was subperitoneal and there was a smaller submucous portion obstructing the lumen of the stomach. There was one smaller submucous tumour present in the stomach. Billroth I partial gastrectomy performed.

Patient has made satisfactory progress since then.

Histological report (Dr. J. Bamforth).—Histological examination of one of the cutaneous lesions showed the typical appearances of a neurofibroma as usually seen

[*November 6, 1946*]

DISCUSSION ON THE TREATMENT OF ACUTE PERITONITIS

Mr. John Morley: I propose to discuss in the broadest terms the treatment of acute peritonitis secondary to infection from the hollow viscera, whether that infection is due to military or civil trauma, to the activities of the surgeon, or to the spontaneous processes of disease.

I am old enough to remember the period of flushing and purging in acute peritonitis. Irrigating fluid under considerable pressure was poured into the peritoneal cavity with the object of flushing out all infective material. The more enlightened used normal saline in this misguided effort, others used various antiseptic fluids of varying degrees of toxicity, but the result was almost uniformly disastrous. If the patient did not succumb to shock, which was usually profound, the invading organisms were spread through the peritoneum, and the reflex inhibition of intestinal movement was made more complete. Then, warming to his work, the surgeon would attempt to overcome the intestinal paralysis by heroic doses of purgatives, repeated hourly "until something happened". What usually happened was the death of the patient, preceded in some cases by a futile enterostomy. About this period there was a great belief in the efficacy of drainage, and the patient with peritonitis would be left bristling with tubes in various quarters of his abdomen, though Nature soon sealed them off, if she was granted time, and they drained little but their own track.

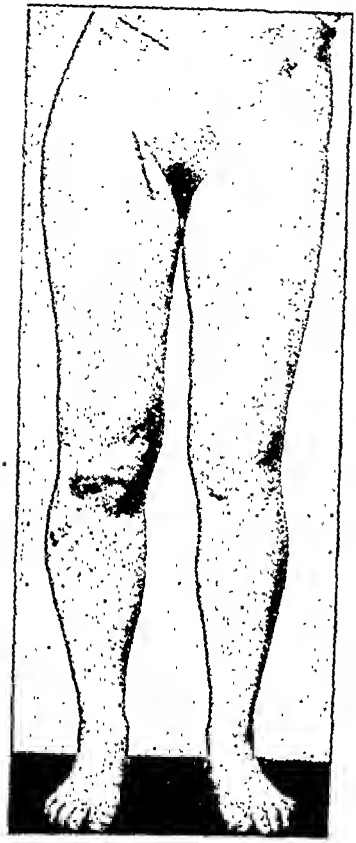
It was a great step forward when this vigorous and ill-advised flushing was abandoned, and gentle sponging of the peritoneal cavity with swabs rung out of warm normal saline took its place, later to be replaced by suction. Spinal anæsthesia, by means of which the surgeon gained the most complete relaxation and ease of access, came into more general use.

But the greatest advance in treatment about this time was the realization of the important part played in peritonitis by loss of water and sodium chloride from the blood; and the practice of replacing them by normal saline given at first *per rectum* or subcutaneously, and later by the intravenous route.

A further step forward came with the introduction of the Ryle's tube. Designed for gastric analysis, it was soon applied to gastric and duodenal suction in peritonitis and intestinal obstruction, with great relief from distension and vomiting.

Sir Henry Dale's discovery of the fundamental part played by acetylcholine in the augmentor mechanism of the gut brought about a certain tendency to revert to the fashion of purging in peritonitis, though now the purging was done with a hypodermic syringe. For a time acetylcholine, eserine, or pitressin were largely used in the hope of overcoming the intestinal inertia of peritonitis, but the results were on the whole disappointing, and we soon came back to the practice of relying chiefly on intravenous fluid, gastric or intestinal suction, and avoidance of fluids by the mouth, giving the antibacterial defences of the body a chance to do their beneficent work unhampered. (In milder cases those drugs that stimulate peristalsis undoubtedly have their use.) And then came the crowning mercy of chemotherapy, first with the sulphonamides and later with penicillin.

Principles of treatment.—Since the vast majority of the cases of peritonitis we are called upon to deal with are secondary to perforations of the alimentary tract, I would put first the closure of the perforation. This means most commonly in civil practice, the removal of a perforated appendix or suture of a perforated duodenal ulcer. If the patient is already showing signs of dehydration, intravenous bandage. *During her stay she was treated ineffectively by deep X-ray and later radon ointment.*



NOTE: (1) The increase in length of the right limb illustrated by the difference in height of anterior superior iliac spines marked with crosses. (2) Increase in girth. (3) Chronic ulcer in the centre of the lower and larger hæmangioma, with two large tortuous arteries medial to the ulcer.

On direct questioning.—She has 5 hæmangiomata around her right patella, which have enlarged proportionally with her general growth.

On examination.—Right Leg: Within 2 in. of the patella lie five dull bluish cutaneous hæmangiomata. In the centre of the largest one (2½ in. × 2½ in.) below the patella, is a typical chronic ulcer (1 in. × ¾ in.).

The whole region of the knee is enlarged, soft, boggy and gently pulsatile. Two large tortuous arteries are visibly and palpably pulsatile on the medial aspect of the ulcer and passing beneath it. A loud high-pitched systolic murmur is present, maximal over the ulcer and on the lateral side of the knee-joint and propagated above the mid-thigh and below as far as the ankle.

Measurements of Limbs.—

Length: Left leg 33 in., right leg 34 in., the increase being equally shared by tibia and femur.

Increase in girth: Thigh 1 in., lower leg ¾ in., knee-joint 1¼ in.

Straight X-ray.—Right femoral condyle ⅛ in. wider than left. No bony rarefaction.

Arteriogram.—14 c.c. Diodone were injected with the femoral artery controlled proximally to site of injection. The concentration of the dye in the tortuous vessels was too poor to reproduce adequately in photographic form. The extent of the lesion was from 3 in. above to about 3 in. below the patella. Three of the large vessels of the aneurysm were of the order of size of the radial artery.

Cardiovascular system.—Heart: Auscultation—no accompanying murmurs. Size—normal clinically, and by X-ray and screening.

Blood: R.B.C. 5,000,000 / c.mm. Hb. 95%.

Blood-pressure and pulse-rate.—At rest, B.P. 135/60; P.R. 82/min. Right femoral artery occluded, B.P. 150/100; P.R. 80/min. Left femoral artery occluded, B.P. 140/65; P.R. 80/min.

Mr. A. Dickson Wright: These arterial types of arteriovenous aneurysms of the legs are very serious cases, liable to terminate fatally from massive hæmorrhage from the associated ulcer during sleep. They frequently end with amputation and often it is hard to get above the pathological condition so that trouble develops in the stump. For this case I would recommend exposure of the femoral artery from groin to the popliteal space with ligature of every branch of the exposed artery. The circulation to the foot is thus assured while the cirsoid vessels are deprived of their arterial connexion.

Chemotherapy.—While everyone will agree that chemotherapy gives us an additional weapon of great value, there is still no approach to unanimity as to which is the best drug to use, or as to the best manner of its application. Intraperitoneal sulphonamides have been widely used with some very promising results. It will be generally agreed that it is a bad practice to dump masses of sulphonamide powder into the peritoneum. It becomes walled off in clumps by adhesions, and these may be a real danger later. A sounder method is to introduce the powder stirred up in normal saline. But what drug? Vaughan Hudson and Smith recommend 15 to 20 grammes of sulphanilamide suspended in 60 to 70 c.c. of normal saline, and with this drug they reduced their mortality in grave general peritonitis and resection of gangrenous gut from 55% to 8·3%. Gardiner rather favours sulphapyridine, also suspended in saline, as it showed the slowest absorption rate and lowest toxicity of any drug he employed.

Young and Warren Cole use phthalyl sulphathiazole or succinyl sulphathiazole intraperitoneally on the grounds that they produce no adhesions and are lethal to coliform organisms.

Fauley *et al.* produced experimental gangrenous appendicitis in dogs by ligating the blood-vessels of the appendix, and obtained strikingly successful results when treatment by intramuscular penicillin was started one hour after the operation.

George Crile, Junior, has recently described a series of 50 cases of peritonitis, either general or local, secondary to appendicitis, treated by 100,000 units of penicillin every two hours for several days, with remarkably good results. There was only one death, from mesenteric thrombosis, and in all the others the infection was controlled by penicillin.

The prophylactic treatment of post-operative peritonitis.—In conditions involving partial obstruction, such as carcinoma of the colon, the fear of intraperitoneal leakage and fatal peritonitis has in the past dictated the custom of operating in multiple stages, starting with a colostomy for the relief of obstruction. Where obstruction is not too complete, most surgeons are finding that succinyl sulphathiazole or phthalyl sulphathiazole given by mouth in adequate doses for three or four days before operation causes such a reduction in the bacterial flora of the gut that primary resection and suture can be carried out with impunity in many cases where it would have been fatal before the use of these drugs. They may well be supplemented by intraperitoneal sulphonamides, but the relative sterilization of the bowel contents is the main objective.

Within recent months, we have witnessed two vigorous tugs at the pillars of the house of surgical orthodoxy. I refer, of course, to Spalding's attack on the time-honoured Fowler position, and Hermon Taylor's advocacy of the non-operative treatment of perforated peptic ulcer. In my view the theory that the Fowler position is the best position to protect the patient from subphrenic abscess formation and from post-operative chest complications does not emerge unscathed from Spalding's attack. Without subscribing to all his arguments about the hydraulics of the subphrenic spaces, I am impressed by his contention that the pneumoperitoneum that follows laparotomy is a source of pain and limitation of breathing in the Fowler position, for I know that pneumoperitoneum induced for radiography of the solid viscera produces marked shoulder-tip pain if the patient sits up, but little or no pain while he is recumbent. I do not follow him in his argument that the Fowler position is uncomfortable to the patient. To my mind, it is too comfortable, and as the nurse is apt to think that his chest is safe in that position, the patient is allowed to lie still for hours with the base of his lungs immobile, and the veins of his calves stagnant, when what he needs for both lungs and limbs is very frequent movement and change of position.

By Hermon Taylor's plea for the expectant treatment of perforated peptic ulcer as a routine I find myself much less convinced. One may concede that in a saline or plasma, with gastric suction by a Ryle's tube, should be started an hour or two before the operation.

The operation itself, necessary though it is, inevitably adds somewhat to the risk of paralytic ileus. If we examine any case of diffuse peritoneal irritation, such as a perforated duodenal ulcer with widespread escape of duodenal contents into the peritoneum, we find from the first a silent abdomen on auscultation. This silence is not due to paralysis of the gut at first, but to active inhibition of all movements by the splanchnic inhibitory reflex. The afferent nerves of this reflex are the sensory fibres supplying the parietal peritoneum, and the efferent nerves are the sympathetic inhibitory fibres to the gut. It is in essence a beneficent protective mechanism, evolved to prevent diffusion of septic material in the peritoneum by the ceaseless movements of the small intestines. Only later, when the gut is distended with gas and fluid, and œdematous from inflammatory changes and failing circulation, does its wall become truly paralysed, and there comes a stage when the paralysis is irreversible by any treatment and the only end is death. The term paralytic ileus emphasizes this terminal stage. I prefer the term *inhibitory* ileus which emphasizes the initial stage, when treatment can do some good.

Now Nature, in evolving the splanchnic inhibitory reflex, took no account of surgical intervention. Every time we open the abdomen and traumatize the sensory nerve-endings in the parietal peritoneum we bring this reflex into action—hence the post-operative "wind" pains after any abdominal operation. Where peritoneal irritation has already produced an inhibitory ileus, our incision adds to the stimulus and increases the tendency to ileus. The best way to avoid this (though only in part) is to operate under spinal anæsthesia, which blocks the inhibitory reflex for the duration of the anæsthesia. In proof of this, one may see intestines bathed in pus contracting in active peristalsis, when exposed under a spinal anæsthetic, though this does not occur in the later stage of true intestinal paralysis.

There is a fundamental difference between this inhibitory or paralytic ileus (sometimes, but not very happily, called adynamic ileus), and mechanical ileus. Peritonitis often leads to mechanical ileus by causing fibrinous or fibrous adhesions that result in kinking, torsion or compression of the bowel. Here we do not find at first the silent immobile abdomen, but noisy exaggerated peristalsis and the colicky intermittent central pains of obstruction. Only in the terminal and hopeless stage of mechanical ileus do we find the silent abdomen.

It is in mechanical ileus due to recent adhesions that the Miller-Abbott tube has proved invaluable, provided that one is reasonably sure there is no strangulation of the gut. It is also of great value in inhibitory ileus if one can get it through the pylorus, but this is often very difficult. Happily, however, a Ryle's tube in the stomach with continuous suction, though somewhat less effective than the Miller-Abbott tube, works very well. The use of the Miller-Abbott tube has practically superseded enterostomy.

To return to the operation: It is carried out with the least possible trauma. This means, in addition to spinal anæsthesia, an adequate incision, and suction rather than sponging to cleanse the peritoneum of infected fluid.

Should the peritoneum be drained? In perforated peptic ulcer, I have not drained a case (apart from subphrenic abscess) for the last twenty years, and I am sure drainage is unnecessary and likely to give rise to the most dangerous form of adhesions. In peritonitis from a gangrenous appendix, I do not drain the peritoneum unless an abscess cavity is very prone to bleed, and then only for twenty-four or forty-eight hours, but I always drain the contaminated abdominal wall. In general, I believe that drainage of the peritoneum does very little good, and that the peritoneum can be trusted to destroy any organisms that are left when the perforation has been closed and gross fluid sucked out. But when in doubt, there is no great harm in draining for a day or two.

In addition in acute peritonitis as in any other infective process, the albumin globulin ratio of the plasma proteins changes; the albumin level falling and the globulin level rising. The importance of this is that the plasma globulins exert an osmotic pressure which is only about one-third of that exerted by an equivalent quantity of plasma albumin.

	BURN 1	BURN 2	BURN 3	VOMITING 1	VOMITING 2	VOMITING 3	PERITONITIS 1	PERITONITIS 2	PERITONITIS 3	PERITONITIS 4
R.B.C.	4·5	6·0	4·5	4·5	6·0	4·5	4·5	6·0	4·5	4·5
Plasma protein	7·5	7·5	5·0	7·5	10·0	7·5	7·5	7·5	5·0	7·5

The accompanying diagram illustrates the effect of acute general peritonitis on the blood volume, the packed cell volume or hæmatocrit reading, and the protein content of the blood. It compares these with the changes which occur in burns and severe vomiting. The height of each column represents the total blood volume, the spotted area the red and white blood corpuscular volume, the clear area the water, salt content, &c., and the black area the plasma proteins. Column 1 under each heading is the normal. Column 2 indicates the position after fluid and protein loss have reduced the blood volume. Column 3 shows what happens after the blood volume has been restored by glucose saline infusion; column 4 demonstrates the theoretical state of affairs after giving both plasma transfusions and glucose saline infusions to a patient with acute general peritonitis. The figures below indicate the red blood corpuscular count and the plasma protein level.

It will be seen that the changes in acute peritonitis are a combination of those found in burns and severe vomiting. The initial hæmoconcentration results in a raised packed cell volume or hæmatocrit reading, and a plasma protein whose percentage is unchanged although a reduction of the total quantity of protein in circulation has occurred. If this hæmoconcentration is corrected by glucose saline alone, the plasma protein level will fall as the blood volume rises. However if both glucose saline and plasma are given it can be maintained at the normal level.

This is of great clinical importance, and in my opinion a plasma transfusion should be given to every patient whose peritoneal infection is sufficiently severe to require an intravenous infusion. For, not only will it prevent the onset of the peripheral circulatory failure from which these patients may die, but if given in sufficient quantity it may even correct established peripheral circulatory failure in an apparently moribund patient.

Another and very important aspect of such plasma transfusions is that, provided the function of the heart remains satisfactory, pulmonary œdema is less likely to occur than with a glucose saline infusion. For the colloid osmotic pressure of the blood is maintained at the normal level, which pressure will oppose the passage of fluid from the blood-stream into the pulmonary alveoli.

During the past three years I have treated 31 patients with established general peritonitis on a post-operative regime of gastro-intestinal aspiration, plasma transfusion, glucose saline infusion, parenteral penicillin, and chemotherapy with a sulphonamide. Of these 31 patients, 25 were treated before signs of peripheral circulatory failure had occurred, and each patient received an average of 2 pints of plasma and 4 pints of glucose saline a day until intestinal activity was re-estabpatient who is a thoroughly bad risk by reason of bronchitis or cardiac weakness it may be preferable to try expectant treatment, and that gastric suction is a valuable safeguard in such a case, but in the average patient with early surgical closure under spinal anæsthesia, the mortality is negligible. Except for one case who had perforated five days and had a subphrenic abscess, I have not lost a patient with a perforation in the last 24 operated on in private. In my Unit during the past five years we have had 100 acute perforations with 8 deaths, but all these deaths were either in patients who had perforated over twenty-four hours before admission (2 cases) with very copious escape of fluid, or, if early, were bad risks by reason of chronic bronchitis and emphysema or old age.

My main contention is that by Hermon Taylor's method, it is impossible to be sure that the gastric suction is preventing the escape of duodenal contents into the peritoneum in dangerous amounts. The stomach may be sucked dry, but a stenosis or spasm at the pylorus may so shelter the perforation in the duodenum from the effect of the suction, that bile and duodenal contents pour out in lethal quantities. And we know that although this fluid may be sterile at first, it soon becomes infected, and the peritonitis may go on to fatal paralytic ileus. One feels little anxiety about an early perforated ulcer that has been closed securely by suture, but I could not sleep at night if I were wondering to what extent leakage might be going on under the gastric suction régime. I believe expectant treatment is only justified in bad-risk cases, and for them it is a definite advance in surgical technique. Hermon Taylor states that the orthodox surgical practice is to suture the perforation and *drain the peritoneum*, but surely drainage for these cases has been abandoned as being both unnecessary and dangerous.

Mr. C. G. Rob: *Protein balance in acute peritonitis.*—Recovery from established acute general peritonitis whilst it is dependent to a certain extent upon the skill of the operating surgeon, is governed to a far greater degree by the pre-operative and post-operative care which the patient receives. I intend therefore to discuss one factor in the ward care of these patients. This factor is protein balance.

During the late war surgeons were interested in protein balance, and a large amount of research was undertaken with particular reference to protein metabolism in wound healing, burns, and wound shock. Amongst these investigations the easily estimated plasma proteins received considerable attention, and some surprising facts came to light. For example the patient with chronic long-standing wound sepsis usually has a normal plasma protein, although a very considerable total loss of protein has occurred; presumably the blood protein level is kept up at the expense of the tissue proteins. However, in acute diseases such as burns or acute peritonitis the plasma protein level may fall before the tissue proteins can be mobilized to replace the loss.

Patients with acute general peritonitis suffer from a reduction of the body protein, which progresses with the disease until it becomes apparent as a fall in the plasma protein level. This reduction of the body protein occurs in four main ways:

(1) As exudate from the surface of the inflamed peritoneum which surface is equal to the cutaneous surface of the body. (2) Into the lumen of the distended intestine when paralytic ileus has occurred. (3) Into the serous and subserous layers of the peritoneum due to vasodilatation and inflammatory œdema. (4) Due to an associated reduction of protein digestion.

Denig's Operation for Trachoma: Two Cases.—Noah Pines, M.B.

Dr. Pines demonstrated a man aged 73, with a gross pannus trachomatosus of the left eye from which he had suffered for over six years. Pines saw him first at the London Jewish Hospital ten days ago and intends to perform Denig's operation on the eye.

The other case was a woman aged 55, who twelve years ago presented a similar picture on her right eye and was operated at the same hospital. Denig's operation proved to be successful and the cornea since then remains clear; the eye quiet. The transplanted mucosa of the lip is still intact from 9 o'clock to 3 o'clock.

Usually the reported cases in the literature were observed for one to three years and this is one of the longest so far reported.

Denig (1911) operated first in 1910, following the work of Ichikawa, who proved the continuity of trachoma from fornix through the conjunctiva bulbi and so to the cornea. He transplanted first the conjunctiva of the healthy eye, but soon changed to the mucosa of the lip. In the first few years he performed 42 operations with 8 recurrences and failure of the mucosa to heal up on the eye in 5 cases. Ogata in 1930 saw good results from the operation in 95 cases. L. Pines in 1931 reported his results in 406 cases, with no improvement in 42 and recurrences in 16. The ætiology of pannus—by continuity or by contact—is still debated. Parsons (1942) is against the continuity, and so is Fuchs (1933). Wolff (1944) and Duke-Elder (1938) hold that there is a simultaneous infection of the cornea and conjunctival fornices. Prokrowsky and Taborisky (1914) (Ophthalmological Congress, Moscow, 1913) were partisans of continuity. A new point of view is brought in by Filatoff (1945) who ascribed the good result of the operation to the stimulant effect of transplanted mucosa. He even implants under the conjunctiva bulbi a belt from the pieces of sclera, taken from a cadaver, preserved for a few days, at the temperature of 4° C., and claims good results. He is also favourably impressed by the result of the operation. Indications for the operation are very few. The chief one is the intractable pannus and pannus crassus. On the whole, MacCallan is right, that usually pannus improves with the general improvement of the trachoma.

lished, the plasma being given as a prophylactic against a possible fall in the blood protein level and the resultant circulatory failure. Not one of these patients developed any sign of peripheral failure and all made a satisfactory recovery.

The remaining 6 did not receive a plasma transfusion until after peripheral circulatory failure had developed, they were moribund with a very rapid thready pulse, a subnormal temperature, a cold clammy skin, and a clear mentality. But in spite of this 3 recovered, their recovery being due I have no doubt to the very large quantities of plasma which they received. Total volume of plasma which each patient received was spread over several days, and consisted of an initial large and rapid plasma transfusion of 4 to 8 pints, followed by an average intravenous fluid intake of 6 pints per day including a maintenance dose of plasma. Feeding by mouth was restarted as soon as the abdominal condition would allow.

In conclusion, whilst the vast majority of patients with acute peritonitis recover without the aid of a drip or suction, the minority with acute generalized peritoneal inflammation need all the help that we can give them, if they are to get better.

These seriously ill patients lose a great quantity of protein, which loss can only be corrected by the intravenous route. I therefore recommend that every patient whose peritonitis is so bad that an intravenous infusion is necessary, receives plasma as a prophylactic measure against the peripheral circulatory failure from which these patients so often succumb, and that the moribund peritonitis patient with a rapid thready pulse and cold clammy skin is given a chance by energetic plasma transfusions. For patients up to middle age the results may be dramatic.

See ELMAN, R. L., LISCHER, C. (1943) *Internat. Abstr. Surg.*, 76, 503.

Mr. R. Vaughan Hudson: *Prophylactic use of sulphonamides.*—Collier and Jackson have shown that after the implantation of an intraperitoneal sulphonamide, the concentration in the portal vein was three to four times that of the blood-stream. This observation produced evidence that toxins and bacteria from the general abdominal cavity were conducted by this route, and reaffirmed our surmise that a great deal more was happening in the hepatic and renal tracts than could be deduced from examination of the systemic blood-stream.

Parenteral penicillin.—One had at first regarded penicillin in the light of closed lesions which had occurred within the intact peritoneal cavity, and failed to appreciate that where an injury had occurred from the outside pyogenic organisms were swept in with the missile; surgical incision can be regarded in the same light, and prolonged drainage also invites the entry of pyogenic organisms.

In this respect penicillin is proving to be most successful in preventing secondary infection of the surgical incision, and secondary infection of essential drainage-tube sites. Moreover, its great value is in the prevention, or control, of the thoracic complications so commonly occurring in the surgery of acute abdominal lesions. This latter is particularly gratifying as sulpha-therapy has been so disappointing in the prevention and treatment of these pulmonary lesions.

Perforated ulcer.—I have had five cases of perforated ulcer in which the patient has refused surgery but has recovered. The interesting factor was the typical complication of post-perforative basal collapse and pneumonia which gave rise to great anxiety in convalescence.

Suction drainage.—I feel that Hermon Taylor has made us appreciate still more the value of suction drainage, and whether the surgeon decides upon non-operative, or operative measures, it is suction drainage that will prove to be the essential factor in reduction of mortality.

Lastly, I wish to emphasize the extreme importance of diagnostic straight X-rays of the abdomen, and their great value in the post-operative management of the physiological recovery of the alimentary tract.

or silkworm gut. The stitches were tied up and the shield put over it, and at the end of a week the stitches were cut.

Sir Stewart Duke-Elder said that Mr. Williamson-Noble was to be congratulated on a successful result of a complicated operation. He had seen quite a number of these devices for artificial eye implants of which there were all sorts of modifications. As far as he could make out this was one of the most satisfactory. One difficulty, however, which had been met with was that after a considerable time—something like eighteen months or two years—some of these plastic implants began to excite a reaction and become loose. Perhaps in these cases the plastic used was of an irritating type. In the Army a plastic implant was used to a considerable extent, but some difficulty was experienced in getting a material which did not cause a reaction. In America instead of a plastic, tantalum had been recently used—a metal which was entirely inert to the tissues. As far as could be seen—they had not been using it for very long—there was much less reaction with tantalum, and, theoretically at any rate, it should be better than an unsuitable type of plastic over a long time. The great drawback to all these operations was the length of time taken. He did not know how long Mr. Williamson-Noble took over the implant.

Mr. Williamson-Noble: About thirty-five minutes.

Sir Stewart Duke-Elder said that the time was shorter than in those cases of which he had had experience.

Mr. Williamson-Noble added that Mr. Hamblin had made an implant for him which was very good and was hoping to produce them in quantity. Mr. John Weiss had produced some differently coloured threads in silk.

The President: Could you use catgut ?

Mr. Williamson-Noble: It might be possible, but there would be more reaction with it. There was very little reaction after this operation.

Ophthalmo-neurological Symptoms in Malignant Nasopharyngeal Tumours. [*Summary*[1]]

By Erik Godtfredsen, M.D.Copenhagen

Malignant nasopharyngeal tumours, though rather infrequent, are by no means rare. Over 2,000 cases have now been published in the literature. Personally, I collected 454 cases over a period of ten years from four Scandinavian radiological clinics: Radiumhemmet, Stockholm and the Radiological Clinics of Lund, Copenhagen and Aarhus, which together serve a population of 7½ million people. The frequency of malignant nasopharyngeal tumours constituted 1% of the total number of cancer cases, i.e. a frequency of the same relative magnitude as that of choroidal melanosarcoma.

As, however, only the cancer cases that are likely to respond to irradiation are referred to the radiological clinics, a correction must be made for this percentage to ascertain the frequency among the total number of cancer cases in the population. The figure then arrived at is 0·4% of all cases of cancer.

The frequency figures for each year show a definite rise in the annual number of cases in the course of the decade in question (a rise of about 40 cases yearly).

38% of the patients presented ophthalmo-neurological symptoms.

Histopathological examinations revealed both carcinomas and sarcomas, in conformity with the fact that malignant nasopharyngeal tumours arise from the mucous membrane and the lymphatic tissue in the nasopharynx.

Age-incidence.—All age-classes from 4 to 79 were represented, but half of the patients were found within the age-classes of 41 to 60. One-fourth of the patients were 40 years of age or younger.

For no discoverable reason there were twice as many men as women.

Symptomatology of Malignant Nasopharyngeal Tumours [454 Cases]

There are four well-defined groups of symptoms: (1) Ophthalmo-neurological symptoms due to the infiltrative growth of the primary tumour or its metastases

---

[1] To be published in full, *Brit. J. Ophthal.*, 1947.

(a) Diabetic Cataract; (b) Endocrine Cataract.—A. LISTER, F.R.C.S.

(a) Mr. Lister said that the first of these cases was a woman aged 36. For several years she had suffered from thirst and polyuria. She had been attending London Hospital since June 1944 for diabetes. In 1944 the sugar tolerance test showed fasting blood sugar, 332 mg. per 100 c.c.; ¾ hour, 400 mg. per 100 c.c., and 2 hours 364 mg. per 100 c.c. She had been on insulin since first attending. On examination both eyes were healthy apart from the following changes in the lenses: between the zone of disjunction and the surface of the adult nucleus at the front and back of the lens (i.e. throughout the cortex) were numerous small whitish-grey opacities interspersed with iridescent particles, some of which were coloured. The nuclei were clear; the fundi were normal, and the vision in each eye was 6/24.

(b) The other case was a patient aged 55, in whom the diagnosis was cataract due to endocrine disturbance. The patient had been attending the London Hospital for some months with glycosuria, which was controlled by diet. There were no other abnormalities apart from obesity. The family history showed that four sons were alive and well, and brothers and sisters were well. The mother had bad eyes.

On examination of the patient both eyes were normal except again for certain lens changes. Between the zone of disjunction and the nuclear surface were numerous opacities varying in size and shape. The large ones were best described as snowflakes, of which there was an accumulation at both posterior poles. The smaller opacities were, many of them, coloured and gleaming. Vision was 6/36 in each eye.

In some comment on both these cases Mr. Lister said that they showed points of similarity to each other and to other conditions in which there was endocrine disturbance of some kind. Mr. Goulden had described a number of such cases (1928, *Trans. ophthal. Soc. U.K.*, **48,** 97). The points of similarity and the points which distinguished these cases from senile and pre-senile forms of cataract were: (1) The appearance of the opacities; some being large and white, and others small, iridescent, and coloured; (2) their distribution, which was throughout the cortex; and (3) the freedom of the nuclei from opacities.

The first case was, he thought, a true diabetic cataract. Although diabetes and cataract were often associated, the cataract was, in the vast majority of cases, senile in type, and the association probably coincidental, but occasionally diabetic cataract similar to the one he was discussing was seen. He was doubtful about the other case. The patient was older—she was 55—and the opacities were larger than were found in true diabetic cataract. She was obese and had a slightly myxœdematous appearance. He would suggest that in her case the lens changes were due to myxœdema.

Plastic Implant into Socket.—F. A. WILLIAMSON-NOBLE, F.R.C.S.

This was a case of an operation for enucleation described by Cutler (1946, *Arch. Ophthal.*, **35,** 71) and adopted by the U.S.A. Medical Service. The plastic implant was designed to promote the fitting of a glass eye or plastic eye into the cavity. In appearance the plastic implant was rather like a small wastepaper basket. By means of a series of epidiascope pictures Mr. Williamson-Noble illustrated the stages of insertion. The stitching material with two needles was threaded through two holes at the bottom, and then up through the 12 o'clock and 6 o'clock positions. Two other sets of sutures were inserted, and the threads brought through a lucite stud, so that when they were tied, the conjunctiva was carried by the stud into the concavity of the basket. In view of the complexity of the suturing, it was desirable to use stitches of different colours. He thought it was an improvement on the ordinary glass or gold ball. He had found it best to use some sort of nylon trigeminus are found in practically all cases. There is a change in frequency between eye nerve lesions and trigeminus lesions at the three stages of the disease.

TABLE II.—INCREASE IN FREQUENCY (%) OF OPHTHALMOLOGICAL SYMPTOMS COMPARED WITH THAT OF TRIGEMINUS LESIONS—FROM THE FIRST SYMPTOM TO THE FULLY-DEVELOPED PICTURE.

	1st symptom 11 months before diagnosis is made %	Initial picture 4 or 5 months before diagnosis is made %	Fully developed picture when the diagnosis is made %
Frequency of ophthalmological symptoms ..	14·4	51·0	75·2
Frequency of trigeminus lesions	71·0	70·0	68·0

Table II shows that the purely ophthalmological complaints constitute a small percentage of the first symptoms, while the trigeminus lesions are in great majority. But at the second stage of the analysis (four or five months before the diagnosis is made) the ophthalmological symptoms increase very considerably, being now found in half of all the cases, whereas the percentage of trigeminus lesions has hardly changed. The increase in the frequency of ophthalmological symptoms continues—though less abruptly so—up to the point of time at which the diagnosis is made, comprising by that time 75·2% of the cases. They are then more frequent than the trigeminus lesions, which remain at a stationary level 68%.

It should therefore be possible to diagnose these cases without waiting for the appearance of the later symptoms. The first symptom—occurring about ten or eleven months before the diagnosis is made—is usually (71·0%) trigeminal neuralgia in the maxillary area. This may be combined with either nasal stenosis, metastatic cervical glands or tubal occlusion. The only ophthalmological symptom at this stage is abducens paresis; there is no other symptom.

By the time of the second analysis—four or five months before the diagnosis is made—there is not only a quantitative, but also a qualitative increase in the purely ophthalmological symptoms. There are no essential qualitative differences between the ophthalmological symptoms of the second and third stages. The purely monosymptomatic ophthalmo-neurological cases are few (3%) at this stage, since forms combined with rhinological or otological symptoms and metastatic cervical glands respectively are found in 40% each of the cases.

Accordingly a patient who at this stage of the disease applies to an ophthalmologist on account of eye muscle paresis, visual disturbances, or exophthalmos, with or without trigeminal neuralgia, will present symptoms also from the other main groups mentioned here. When the ophthalmologist is consulted by patients suffering from abducens paresis, impairment of vision, exophthalmos, or Horner's syndrome he should always suspect a malignant nasopharyngeal tumour. Palpation for metastatic cervical glands, and questioning as to rhinological or otological symptoms, and possibly an oto-rhinological special examination will help to confirm the diagnosis.

TABLE III.—NATURE AND FREQUENCY OF OPHTHALMO-NEUROLOGICAL SYMPTOMS IN 172 PATIENTS WITH MALIGNANT NASOPHARYNGEAL TUMOURS.

Eye symptoms 129 patients 75·2%	Alone 40 patients 23·4%	Ophthalmoplegia..	22 patients
		Ophthalmoplegia + II	11 patients
		Ophthalmoplegia + Horner ..	3 patients
		II-lesion alone	2 patients
		Exophthalmos	2 patients
	With V-lesion 44 patients		25·6%
	With other cranial nerve-lesion, partly V. 45 patients		26·2%
V-lesions 117 patients 68·0%	With eye symptoms 78 patients		45·4%
	Without eye symptoms 39 patients		22·6%

into the base of the skull and adjacent regions; (2) rhinological and (3) otological symptoms due to the exophytic growth of the primary tumour into the nasopharynx affecting the Eustachian tube; (4) enlarged cervical glands from lymphogenous metastases.

The early symptoms are important.

The first analysis covers the first symptom(s) observed by the patient. This appears on an average eleven months (three or four years at most) before the exact diagnosis is made.

The second analysis covers the initial signs and symptoms in a wider sense. At this stage there are several symptoms within one group, or different groups are represented. This pathological picture is seen on an average four or five months before the exact diagnosis is made.

The third analysis covers the fully developed picture, and corresponds to the time at which the diagnosis is made and the patient referred to a radiological clinic.

The percentage frequency of ophthalmo-neurological symptoms in these three analyses appears from Table I, which also shows the frequencies of the three other main groups of symptoms.

TABLE I.—PERCENTAGE DISTRIBUTION OF THE DIFFERENT GROUPS OF SIGNS AND SYMPTOMS AT THREE STAGES OF THE DISEASE AMONG 454 CASES OF MALIGNANT NASOPHARYNGEAL TUMOUR.

	1st symptom 11 months before diagnosis is made	Initial picture 4 or 5 months before diagnosis is made	Fully developed picture when the diagnosis is made
	%	%	%
Ophthalmo-neurological symptoms	16·0	34·8	38·0
Rhinological symptoms	30·8	51·4	56·2
Otological symptoms ..	23·0	48·5	49·1
Metastatic cervical glands	32·6	48·4	74·9

Table I shows that ophthalmo-neurological complaints appear as the first symptom in 16·0% of the cases, while metastatic cervical glands and rhinological symptoms are both present as the first symptom in about one-third of the patients. Otological symptoms are rarer, being present in about one-fifth of the cases only. Nearly all the cases are monosymptomatic at this stage of the disease (in nine-tenths of the cases); and it must be emphasized that two-thirds of the patients did not complain of nasal symptoms.

Second analysis: The most conspicuous changes at this stage are as follows: The ophthalmo-neurological symptoms have more than doubled in frequency, occurring now in 34·8%, whereas the other groups of symptoms present more moderate increases in frequency, each being found in half of the patients. The frequency of monosymptomatic cases has become reduced to one-fourth.

Third analysis: There are two facts which are particularly noteworthy: First the frequency of ophthalmo-neurological symptoms is almost stationary, being found in a total of two-fifths of the cases (or 38·0%), and secondly there is a considerable increase in the frequency of metastatic cervical glands, which are now present in three-fourths of the patients. Oto-rhinological symptoms, on the other hand, are stationary, occurring in about half of the cases.

These analyses show plainly that when ophthalmo-neurological symptoms do occur they appear early in the disease, and they can be sorted out as a special group four or five months before the exact diagnosis is made. They do not—as was hitherto believed—appear only at the advanced and hopeless stage.

NATURE AND FREQUENCY OF OPHTHALMO-NEUROLOGICAL SYMPTOMS

All forms of cranial nerve lesions are met with, as might have been expected from the manner of growth of the tumour. Lesions of the eye nerves and/or

TREATMENT

The treatment of malignant nasopharyngeal tumours is now purely radiological, as there is contra-indication for operative treatment (both from a technical and from a biological point of view) of such deep-seated and invading tumour forms. Fortunately such tumours are generally rather radiosensitive on account of their biologically immature character.

A strong, external, protracted, fractional X-ray or teleradium treatment is given, which on rare occasions is supplemented by a local radium or X-ray treatment. The X-ray treatment is given in anterior and lateral portals in doses of from 4,000 to 10,000 r during from three to eight weeks. This treatment can secure a lasting freedom from symptoms (over five years), but whether it does so depends to a certain extent on the histopathological type of the primary tumour and on the extent of the disease. The radiosensitive reticulum-cell sarcomas, for instance, show a "five-year cure rate" of nearly 40%, while the corresponding figure for the total number of cases amounts to 22·2%.

The Diagnosis and Treatment of Tumours of the Nasopharynx

By E. D. D. DAVIS, F.R.C.S.

TUMOURS of the nasopharynx are difficult and unsatisfactory to treat but fortunately they are comparatively rare. I have studied the notes of 33 of my patients and the literature of a large number of other cases with the object of establishing an earlier diagnosis and more successful treatment. The 33 cases were seen during the past twenty-five years and consisted of: Carcinoma, 19; lympho-sarcomata or lymphomata, 4; angio-fibromata, 9; myxosarcoma of doubtful origin, 1.

These are the types of tumours recorded by other observers but some call the fibroma or angio-fibroma a fibro-sarcoma. Two of the angio-fibromata proved to be sarcomata and recurred some time after removal. This list does not include rare tumours such as ameloblastomas or adamantinomas which extend from the pituitary body along the craniopharyngeal canal or from the maxillæ into the nasopharynx.

The early diagnosis of tumours of the nasopharynx is delayed because they are hidden in a cavity which is sometimes difficult to inspect. This inspection of the nasopharynx in patients who cannot tolerate the small mirror placed behind the soft palate is difficult and also in advanced cases of carcinoma when inability to open the mouth and fixation of the mandible is a symptom. Moreover the patient does not consult a doctor until the growth is large enough to produce a series of mechanical signs which are slow and insidious in onset and when it is too late for successful treatment. Malignant growths within themselves do not produce any specific diagnostic symptoms or signs. Blood changes, cachexia, &c., are of no practical value in the early diagnosis. Gordon New of the Mayo Clinic reported 79 cases of malignant growths of the nasopharynx; 34 were epitheliomata and 33 were lymphosarcomata. Of these 79 patients 74 had had an operation for the relief of symptoms without recognition of the fact that a primary growth in the nasopharynx was the cause of these symptoms. In 24 patients tonsils and adenoids had been removed, in 18 glands in the neck, in 12 the wisdom or third molars had been extracted. Various intranasal operations had been performed in 19 and finally a mastoid operation for the relief of pain.

The symptoms and signs of carcinoma of the nasopharynx vary with the site and type of growth and the commonest site is the lateral wall. When the growth

Table III shows that 75·2% of the cases had ophthalmological symptoms, and that two-thirds of these patients presented trigeminus lesion as well. Correspondingly two-thirds of the 68% with trigeminus lesion presented ophthalmological symptoms as well. It appears from this close connexion between ophthalmological symptoms and trigeminus lesion that the tumour tissue usually affects the area round the cavernous sinus, where—as already mentioned—these cranial nerves run in intimate relation to each other.

The cases with ophthalmological symptoms can be divided into: (1) Purely ophthalmological cases; (2) forms combined with trigeminus lesions; and (3) forms combined with trigeminus lesions together with other cranial nerve lesions, usually lesions of the ninth and tenth nerves.

TABLE IV.—NATURE AND FREQUENCY OF 461 SINGLE NERVE LESIONS IN 172 PATIENTS WITH MALIGNANT NASOPHARYNGEAL TUMOURS.

Nerve lesions	VI	III	IV	II	Horner	V	Others
Frequency	114	42	29	29	27	119	101
%	24·0	9·1	6·3	6·3	5·8	25·7	21·8

It appears from Table IV that eye nerve lesions constitute more than half of the total number of cranial nerve lesions, partly in the form of ophthalmoplegias (39·4%), partly as visual pathway lesions (6·3%), and Horner's syndrome (5·8%). Among the ophthalmoplegias the predominating group is that of paresis of the sixth cranial nerve, which constitutes nearly one-fourth of the total number of nerve lesions, being thus almost equal in frequency to trigeminus lesions, 25·7%.

Pareses of the third and fourth cranial nerves are of much rarer occurrence. The same is the case with pareses of the other cranial nerves (seven, and nine—twelve), which altogether constitute 21·8% distributed over 7 cranial nerves, chiefly the bulbar nerves.

Of the 461 cranial nerve lesions 6·7% were bilateral lesions, which in practically all cases affected the eye nerves. The eye symptoms therefore play a predominant part in the early diagnosis of malignant nasopharyngeal tumours.

The ophthalmoplegias generally manifested themselves as massive paralyses with associated clinical findings. The visual pathway lesions, on the other hand, presented various degrees of severity from a slight impairment of vision to the more frequent total amaurosis with atrophy of the optic nerve or choked disc. Quadrantanopia or hemianopia was of rarer occurrence.

Exophthalmos due to penetration of the tumour into the orbit was found in 19 patients with varying degrees of chemosis and disturbances of motility, generally associated with a poor general state.

The trigeminus lesions are usually neuralgias in one or more of the three branches; the motor root is more rarely affected.

There are multiple cranial nerve syndromes in many of the cases. For example there is one cranial nerve syndrome with ophthalmoplegia (most often sixth nerve paresis) and paresis of the twelfth cranial nerve and usually also trigeminal neuralgia which merits particular attention. As this syndrome was observed in 9 cases, it was scarcely an accidental combination. The ophthalmoplegia and the trigeminal neuralgia are the result of tumour invasion round the cavernous sinus. The paresis of the twelfth cranial nerve, which was present without lesion of other distal cranial nerves (so that diffuse tumour growth can be excluded) is a result of involvement of the lymphatics. Metastatic cervical glands were observed in all these cases, and the primary tumour was often situated on the lateral wall of the nasopharynx so that the enlarged retropharyngeal lymph glands, which lie off the hypoglossal canal, compressed the nerve.

This cranial nerve syndrome is thus conditioned partly by the intracranial growth of the primary tumour, and partly by lymphatic metastases, and is therefore pathognomonic of a malignant neoplasm in the nasopharynx.

All the 19 cases mentioned above derived little benefit from radium or deep X-ray therapy and all of them died from twelve to eighteen months from the first appearance of symptoms. Radium was most unsatisfactory because it caused considerable reaction with pain and irritation of the mucosa and was followed by metastasis. The lymphosarcomata and the lympho-epitheliomata disappeared rapidly with radium treatment but they all died of metastases within two years. However deep X-ray therapy is the only treatment which holds out any hope of success or even relief.

The bleeding fibroma of male puberty is benign and occurs in boys between the ages of 10 and 20. It is a sessile hard globular fixed tumour usually growing from the body of the sphenoid and basi-occipital bone or from the inaccessible roof of the posterior nares. The rate of growth of this tumour varies considerably and it may become so large as to encroach on the antrum, the posterior ethmoidal cells or sphenoid and by pressure produce optic atrophy and loss of sight. At a later stage the tumour broadens the bridge of the nose, displaces the eyeballs forwards, then outwards. At first one eye is displaced and then the other. The result is known as "frog-face". It is very difficult to distinguish this fibroma from a malignant fibro-sarcoma. The sarcoma grows very rapidly, it is softer, not circumscribed, often occurs at a later age. It ulcerates, bleeds spontaneously and also produces the deformity of "frog-face". The histological section shows larger ill-defined blood spaces and many more round cells than the fibroma but diagnosis by the section is not infallible. [Section of fibroma and of fibro-sarcoma shown.] I have come to the conclusion that if a "fibroma" which has been completely removed by enucleation recurs it is probably a sarcoma. In my experience radiotherapy has no beneficial effect on the fibroma or fibro-sarcoma but Figi of the Mayo Clinic has treated a number of cases of fibroma with diathermy and radium implantation with success.

Sir Stewart Duke-Elder said that so far as he knew the literature of the subject, this collection of 454 cases of these rare tumours was by far the largest extant; the only one approaching it—and that a very much smaller collection—derived from the Mayo Clinic. This work was not only a compliment to Dr. Godtfredsen's industry, but also to the medical system of the northern countries, which, although small, were able to surpass in this respect not only our own land but even America with all its efficiency. From his own standpoint the most interesting thing was that 38% of these cases should have shown ophthalmological symptoms, and the interest became really acute when he learned that in 16% the first signs were ophthalmological. It was certainly a disturbing thought that in these conditions, which were often forgotten by the ophthalmologist, the responsibility for early diagnosis which might well be a question of life or death to the patient, was so often primarily ophthalmological. Only that morning he had received a letter from a doctor in Scotland stating that a patient whom he had seen six months ago suffering from an abducens palsy was now showing signs of what the speaker supposed was an advanced and untreatable nasopharyngeal tumour; if he had had the advantage of hearing Dr. Godtfredsen's paper before he saw the case six months ago, he would have been more alive to this possible development. If only for that reason this paper was one of the most important that they had listened to this session.

Mr. D. V. Giri said that Mr. Davis had suggested that the differentiation between a sarcoma and a fibroma was not easily made, and in fact that it could only be established as sarcoma if, after removal, there was a recurrence. But when a section of the tumour was made and examined did it not reveal the nature of the growth ?

Mr. E. D. D. Davis, in reply to Mr. Giri, showed two microscope sections, one of a fibroma and the other of a sarcoma. The sarcoma showed that the blood spaces were not so well is in the region of the Eustachian tube or lateral wall the first symptom may be a unilateral deafness with fluid in the middle ear as the result of Eustachian obstruction. This is known as the auricular type of growth and it was the first symptom and sign in 3 of my 19 cases. Sometimes a diagnosis had not been made until secondary growths appeared in the cervical lymphatic glands. The glandular type of case shows the enlargement of the deep cervical lymphatic glands at the angle of the jaw on both sides of the neck or the superficial cervical group of glands along the posterior border of the sternomastoid.

This was the first sign in 6 cases. This is the type of case for which tonsils had been enucleated or a dissection operation for glands in the neck had been performed before the diagnosis of carcinoma of the nasopharynx had been made. The enlargement of the lymphatic gland is the first sign of a lympho-epithelioma or lymphosarcoma.

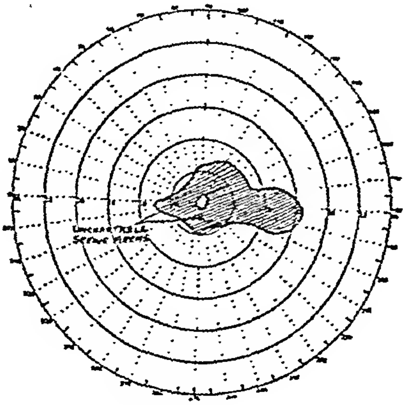
Neurological symptoms such as headache, pain, diplopia and paralysis of cranial nerves, particularly the sixth cranial nerve were the first symptoms in 6 cases. These patients are seen first by the ophthalmic surgeon or neurologist and the primary pharyngeal lesion may escape detection. The headache is bi-temporal or on the vertex of the skull. A neuralgia of the fifth cranial nerve or upper cervical spinal nerves is occasional but otalgia and pain in the distribution of the auriculotemporal nerve are more common. Paralysis of the sixth cranial nerve first on one side and then on both is the commonest. It is followed by ptosis and paralysis of the third nerve and later a complete ophthalmoplegia on the one side and a partial on the other. There is evidence to show that this growth may commence in the body or great wing of the sphenoid and later burrow to the surface in the nasopharynx particularly when a paralysis of a cranial nerve is the first sign and precedes the other symptoms by some weeks. An infrasellar pituitary tumour may resemble a carcinoma of the nasopharynx but pituitary tumours more often produce a bi-temporal hemianopia and other localizing signs.

The superficial lymphatic glands along the posterior border of the sternomastoid are involved early and the removal and section of such a gland reveal a grade 3 or 4 carcinoma. Gordon New has recorded 2 cases of paralysis of the nerves in the jugular foramen with the resulting paralysis of the trapezius, sternomastoid, palate, pharynx and recurrent laryngeal nerve. The growth was found in the lateral wall of the nasopharynx and probably originated in the region of the jugular foramen. A persistent sore throat is said by some to be an early symptom.

Nasal symptoms especially epistaxis or a blood-stained mucous discharge from the nasopharynx accompanied by headache in a patient of cancer age is suspicious, and a careful examination of the nasopharynx with the post-nasal mirror, the endoscope passed through both nostrils alternately and with the finger, should be made. Good illumination and a direct view of the nasopharynx can be obtained by retracting the palate with a special coolite retractor or curved pencil torch. The nasopharynx thus illuminated can be clearly seen when looking through the anterior nares with a large nasal speculum. These methods of examination of the nasopharynx are essential to the early diagnosis of new growths of this area. An X-ray photograph which shows the extent of the growth is useful. Nasal obstruction except in cases of angio-fibroma is not common. When the growth is accessible as large a piece as possible should be removed for a biopsy. This can be done through the nose and the area should be sealed by a small diathermy electrode. Sometimes a metastatic lymphatic gland is more useful for a biopsy.

The treatment of malignant growths of the nasopharynx is confined to deep X-ray therapy. These cases are inoperable and beyond surgery when first seen. Deep X-ray therapy is more hopeful now that an earlier diagnosis is possible and the technique has improved.

of ring shape, with a central seeing island, and much improved visual acuity, and was kind enough to draw my attention to this; I had not seen the patient for six months; previously I had found the usual poor vision and large scotoma.



Sister D. 4/2000 W. July 25, 1946.

I examined her fully on July 25, 1946. The right pupillary reactions were ill-sustained, and the right disc pale. Vision was a full 6/5. There was no peripheral field loss, but the screen examination to 4/2000 showed a central ring scotoma, the seeing island being about 1° in size. There were also two unchartable seeing islands of much lower acuity, in the lower nasal part of the scotoma.

We have been able to find no reference to such development in a case of retrobulbar neuritis, and therefore considered it worthy of report. We attribute the result to recovery of a few central affected fibres, but the well-known vulnerability of the papillo-macular bundle makes the occurrence doubly interesting.

Dr. N. Pines said that he would explain the sudden blindness and the following restoration of the vision by angiospasm. He would suggest that the condition could be elicited by showing the difference in the retinal arterial tension between the right and left eyes.

Denig's Operation: Two Cases.—Noah Pines, M.B.

Case I.—Man aged 54. This case was one of trachoma chronicum cicatricum in which the tarsus of the left eye had been excised eighteen years previously; the incision having been made through the sulcus. The right eye was operated upon —Denig's operation—about twelve years ago, but the major middle part of the graft did not take. March 1944 the left eye showed keratitis pannosa ulcerosa.

January 15, 1946: There had been complete superficial corneal ulceration a week previously, but only the upper part of the cornea was then involved. It was a case of pannus trachomatosus.

January 29, 1946: The eye was better. July 23, 1946: Denig's operation was performed on the left eye, with satisfactory results.

Case II.—Man aged 73 with pannus trachomatosus crassus; previously shown on October 10, 1946.

October 18, 1946: Denig's operation was carried out.

The diagrams (*see* next page) reproduced from Professor Fillatoff's book "Optical Transplant of the Cornea," Odessa, 1945, illustrate the steps of the operation.

defined, and larger and there were many more round cells. A sarcoma often ulcerated and was much softer. Growth was very rapid and if an apparent fibroma recurred quickly after complete removal it was a sarcoma. The difference between the two sections was not conclusive and the diagnosis on the section only might be fallacious.

Sir Richard Cruise said that he had in mind a case which he had watched now for two months. The first symptom was exophthalmos, slight but definite, with retraction of the lid. In about a month the patient came again and he noticed some further development in the symptoms, paresis of outward and upward movements, and again when he came after two months. Were there tumours of this slow-growing character which would produce a slow increase of symptoms of this nature. X-ray photographs, stereoscopic, revealed nothing and an oto-rhinologist had seen the patient and could find nothing wrong with the sinuses. How long would it be possible for such a condition to go before anybody but a pharyngeal expert could decide that this was not a nasopharyngeal growth, or how soon could one expect a positive diagnosis of that nature to be made?

Mr. Lionel Colledge said that although Dr. Godtfredsen's paper had been most interesting, those who had studied the book he had written would realize that what he had given them that evening was only a small part of the knowledge of this subject which he had accumulated. He had attacked the matter on a broad front, and had made an even greater contribution to laryngology than to ophthalmology. His classification into four groups was very important, if only because it drew attention to the fact that only in one-third of the cases were local symptoms present in the early stages. He had also described the symptoms very elaborately, and he had described a syndrome of his own.

This form of disease was brought into prominence about thirty years ago by Trotter when he described a syndrome, later known as "Trotter's triad", in which there was depression of the palate, neuralgia in the lower divisions of the fifth nerve, and deafness. But Trotter described it in only 8 cases, and it only gave a very partial view of the subject, because there was a number of other important symptoms. In those days there was little to be done for the patients. If any operation could have succeeded it would have done so in Trotter's hands, but all his operative attempts were failures. The situation to-day was rather different. In at least 20% of the cases the tumour disappeared permanently on irradiation; in a far larger number it disappeared temporarily, but during the first year or two there were a number of recurrences, and even if there was no local recurrence, a good many of the patients succumbed to fresh deposits in bone, especially in the spine. It was rather an under-statement to say that about one in five gave a lasting good result.

Histological investigation of the problem showed that in this region about half the tumours were epiblastic and about half mesoblastic in origin, a much larger proportion of mesoblastic tumours than occurred in other parts of the body. In addition, many of the epiblastic tumours were classified as lympho-epitheliomas and undifferentiated carcinomas which responded well to radiotherapy. The highly differentiated epitheliomas gave very few good results, but their relative infrequency explained the good results of radiotherapy which was especially effective for lympho-epitheliomas, sarcomas and salivary gland tumours.

Dr. Godtfredsen, in reply, thanked all his colleagues in the Discussion. It had been most interesting to listen to Mr. Davis's experience. The histopathologic distribution was the same as that in his own material, but he (Dr. Godtfredsen) had not gone into the details of these questions in this paper. Sir Stewart Duke-Elder's case had similar features to many cases in his series, and if there had been time enough he could have described many difficult and tragic case histories.

In answer to Sir Richard Cruise he (Dr. Godtfredsen) said that in a small number of cases the primary tumour had a curious submucous mode of growth during a period from six to twelve months where it was impossible to see the tumour by post-rhinoscopic examination.

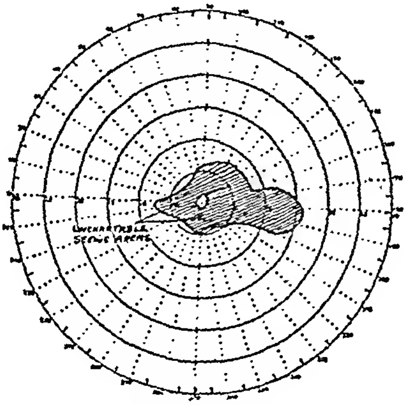
Ring Scotoma after Retrobulbar Neuritis.—FRANK W. LAW, F.R.C.S.

Patient in early middle age.

May 1942: Rapid loss of vision in the right eye; the signs pointed unmistakably to an acute retrobulbar neuritis, and neurological opinion (Dr. Behrman) found reason in the general examination and past history to confirm this diagnosis and attribute the cause to disseminated sclerosis. Vision was lost in five days and for ten days there was no perception of light; slow recovery occurred to counting fingers.

Past history.—She had an attack of vertigo seven years before she developed the neuritis. The attack lasted several days and was accompanied by ataxia for two weeks necessitating her staying in bed. Such a history, Dr. Behrman adds, is by no means uncommon in disseminated sclerosis.

The visual field was examined by Dr. Behrman on four occasions between 1942 and 1946, and the usual picture of a large central scotoma was found, with visual acuity to correspond. On the last occasion, however, he found the scotoma to be of ring shape, with a central seeing island, and much improved visual acuity, and was kind enough to draw my attention to this; I had not seen the patient for six months; previously I had found the usual poor vision and large scotoma.



Sister D. 4/2000 W. July 25, 1946.

I examined her fully on July 25, 1946. The right pupillary reactions were ill-sustained, and the right disc pale. Vision was a full 6/5. There was no peripheral field loss, but the screen examination to 4/2000 showed a central ring scotoma, the seeing island being about 1° in size. There were also two unchartable seeing islands of much lower acuity, in the lower nasal part of the scotoma.

We have been able to find no reference to such development in a case of retrobulbar neuritis, and therefore considered it worthy of report. We attribute the result to recovery of a few central affected fibres, but the well-known vulnerability of the papillo-macular bundle makes the occurrence doubly interesting.

Dr. N. Pines said that he would explain the sudden blindness and the following restoration of the vision by angiospasm. He would suggest that the condition could be elicited by showing the difference in the retinal arterial tension between the right and left eyes.

Denig's Operation: Two Cases.—NOAH PINES, M.B.

CASE I.—Man aged 54. This case was one of trachoma chronicum cicatricum in which the tarsus of the left eye had been excised eighteen years previously; the incision having been made through the sulcus. The right eye was operated upon —Denig's operation—about twelve years ago, but the major middle part of the graft did not take. March 1944 the left eye showed keratitis pannosa ulcerosa.

January 15, 1946: There had been complete superficial corneal ulceration a week previously, but only the upper part of the cornea was then involved. It was a case of pannus trachomatosus.

January 29, 1946: The eye was better. July 23, 1946: Denig's operation was performed on the left eye, with satisfactory results.

CASE II.—Man aged 73 with pannus trachomatosus crassus; previously shown on October 10, 1946.

October 18, 1946: Denig's operation was carried out.

The diagrams (*see* next page) reproduced from Professor Fillatoff's book "Optical Transplant of the Cornea," Odessa, 1945, illustrate the steps of the operation.

defined, and larger and there were many more round cells. A sarcoma often ulcerated and was much softer. Growth was very rapid and if an apparent fibroma recurred quickly after complete removal it was a sarcoma. The difference between the two sections was not conclusive and the diagnosis on the section only might be fallacious.

Sir Richard Cruise said that he had in mind a case which he had watched now for two months. The first symptom was exophthalmos, slight but definite, with retraction of the lid. In about a month the patient came again and he noticed some further development in the symptoms, paresis of outward and upward movements, and again when he came after two months. Were there tumours of this slow-growing character which would produce a slow increase of symptoms of this nature. X-ray photographs, stereoscopic, revealed nothing and an oto-rhinologist had seen the patient and could find nothing wrong with the sinuses. How long would it be possible for such a condition to go before anybody but a pharyngeal expert could decide that this was not a nasopharyngeal growth, or how soon could one expect a positive diagnosis of that nature to be made?

Mr. Lionel Colledge said that although Dr. Godtfredsen's paper had been most interesting, those who had studied the book he had written would realize that what he had given them that evening was only a small part of the knowledge of this subject which he had accumulated. He had attacked the matter on a broad front, and had made an even greater contribution to laryngology than to ophthalmology. His classification into four groups was very important, if only because it drew attention to the fact that only in one-third of the cases were local symptoms present in the early stages. He had also described the symptoms very elaborately, and he had described a syndrome of his own.

This form of disease was brought into prominence about thirty years ago by Trotter when he described a syndrome, later known as "Trotter's triad", in which there was depression of the palate, neuralgia in the lower divisions of the fifth nerve, and deafness. But Trotter described it in only 8 cases, and it only gave a very partial view of the subject, because there was a number of other important symptoms. In those days there was little to be done for the patients. If any operation could have succeeded it would have done so in Trotter's hands, but all his operative attempts were failures. The situation to-day was rather different. In at least 20% of the cases the tumour disappeared permanently on irradiation; in a far larger number it disappeared temporarily, but during the first year or two there were a number of recurrences, and even if there was no local recurrence, a good many of the patients succumbed to fresh deposits in bone, especially in the spine. It was rather an under-statement to say that about one in five gave a lasting good result.

Histological investigation of the problem showed that in this region about half the tumours were epiblastic and about half mesoblastic in origin, a much larger proportion of mesoblastic tumours than occurred in other parts of the body. In addition, many of the epiblastic tumours were classified as lympho-epitheliomas and undifferentiated carcinomas which responded well to radiotherapy. The highly differentiated epitheliomas gave very few good results, but their relative infrequency explained the good results of radiotherapy which was especially effective for lympho-epitheliomas, sarcomas and salivary gland tumours.

DISCUSSION: LEUCOTOMY AS AN INSTRUMENT OF RESEARCH

Dr. A. Meyer and Dr. T. McLardy: *Neuropathological studies* [*Abridged*].—Prefrontal leucotomy, in pursuing its therapeutic purpose, is furnishing us with a human experiment on the function of the frontal lobes on a scale comparable in its potentialities perhaps only with the first world war's head injuries which contributed such a wealth of new knowledge through the work of Head, Holmes, Goldstein and others.

The neuropathological (and neuro-anatomical) is of course only one among the many aspects of this experiment. Valuable opportunities of research are offered in many other fields including neurology, psychology and pharmacology. The neuro-pathological side of the problem is of some special importance because most, if not all, of the clinical research work would be largely invalid without ultimate pathological control.

The importance of pathological control is illustrated by the following table which shows both hemispheres in all our cases at present numbering 27, analysed in terms of the segments involved in the cut. It demonstrates clearly the variability of the lesions and that in only a few cases was the general aim attained of a bilateral lesion

(Case No. 6 was a lobectomy.)

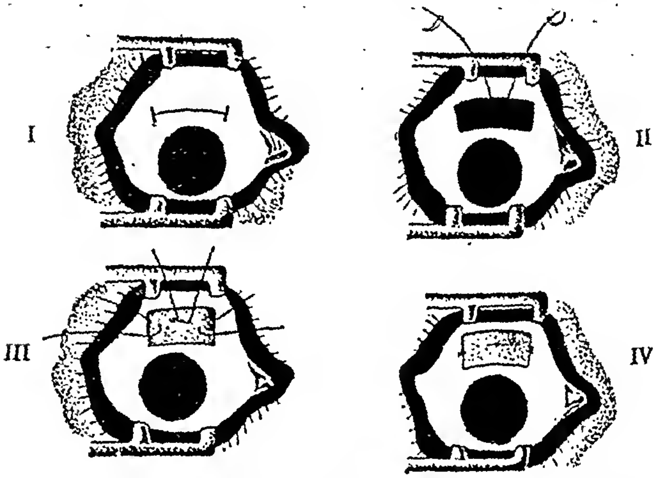

Diagram I.—Incision of the conjunctiva bulbi. Diagram II.—The flap of the conjunctiva bulbi is excised and a stitch is passed. Diagram III.—The flap of the mucosa of the lip now covers the wound and stitches are passed. Diagram IV.—Operation completed.
(*After* Prof. V. P. Filatoff: "Optical Transplant of the Cornea", Odessa, 1945.)

Result of operation.—(1) L.V. Before operation: V.A.—Counting fingers at 2 metres; (2) L.V. After operation: Counting fingers at 4 metres.

Retinal Hæmorrhage with Mitral Incompetence.—NOAH PINES, M.B.

This case of advanced mitral incompetence, which was of many years standing, was in a man aged 34.

October 23, 1946: He helped to move a heavy object, and on the following day developed a troublesome cough. Two days later a large venous hæmorrhage appeared in the left eye at the 6 o'clock position. B.P. was: right arm $\frac{100/90}{60}$ mean 80, oscil. 7; left arm: $\frac{100/90}{60}$ mean 60, oscil. 4.

November 1, 1946: The hæmorrhage in the left eye had completely gone, without leaving any trace, but in the right eye there appeared a fresh striate, rather large hæmorrhage covering the secondary branch of an artery at the 2 o'clock position, already with a white spot in it.

Dr. Pines gave an illustrated account of the instrumental methods used in examination: (1) Bailliart's dynamometer for measuring the retinal arterial pressure; (2) Pachon's oscillometer for measuring the brachial arterial pressure and oscillometry.

The President, speaking of the cases in which Denig's operation had been performed, said that this operation was very successful. He well remembered a case in which he was concerned with another member of the Section many years ago in which the result was very gratifying.

significantly larger in man than in the chimpanzee, in striking contrast to the temporal and parietal lobes which steadily enlarge from monkeys to man. This is supported by the oscillographic work by Kennard and McCulloch (1944). As a corollary to this it is interesting to remember that it is the theta rhythm, now believed to be the normal E.E.G. rhythm of the human temporo-parietal region, which is abnormal in conditions of immaturity, behaviour problems in children and aggressive psychopathy (Hill, 1945) . Furthermore, the temporal lobe possesses the distinction of containing the only cerebral cortex devoid of thalamic projection (Walker, 1938). While these findings do not disprove the preoccupation of the frontal lobes with emotional and personality integration, they cast some doubt on the validity of using gross phylogenetic data in contending that the frontal lobes are man's greatest developmental achievement and therefore likely to be particularly concerned in his highest mental activities.

Serious criticism of the frontal lobe localization has come also from the clinical side. A specific personality change caused by lesions in the frontal lobes has never been generally accepted in this country. Walshe (1931) has recognized a frontal lobe syndrome, but one recalls an earlier joint meeting of this and the Neurological Section when only Gordon Holmes (1931) acknowledged the concept of personality changes due to frontal lobe tumours, whilst Kinnier Wilson, Mapother, Golla, Symonds and Worster-Drought more or less definitely rejected it.

The issue has been quite recently taken up by Hebb (1945) whose critical review on "Man's Frontal Lobes" seems to have aroused lively interest in this country. We agree with several of his critical points, and in particular that in all cases of bilateral pathological involvement or surgical removal of the frontal lobes there is the possibility that the pathological process itself may be more responsible for the mental changes than the loss of frontal lobe tissue. We disagree, however, with his evaluation of Hebb and Penfield's (1940) personal case as an instance of minimal, or even absent, deficit syndrome after bilateral lobectomy. The previous personality of an adolescent, even when known, cannot be taken as a reliable control guide to what his personality would have become after full uninterrupted maturation.

Hebb explicitly rejects the evidence from prefrontal leucotomy because of the uncertainty of the extent of the anatomical defect caused by the surgical lesions and the possibility of undetected pathological complications. He did not perceive that, provided it were possible to obtain a sufficient number of leucotomized brains from patients dying from intercurrent causes, and that clinical and psychological examinations before and after the operation were adequate, then all the conditions which he demands would be fulfilled, although of course it should not be forgotten that leucotomy is not identical with lobectomy. Our material is as yet too limited and too unevenly investigated clinically, as well as pathologically, to fulfil these conditions; but even a provisional analysis gives some concrete idea of the potentialities of such an investigation, as the following brief survey may indicate.

In 6 out of the 19 patients who survived long enough for adequate clinical observation (from seven weeks to almost four years) symptoms of a frontal lobe deficit syndrome, such as euphoria, facetiousness, apathy, lack of initiative or overactivity, were recorded. In these cases we found little evidence of pathological changes different from those in the other cases, which might have caused the syndrome. In others of the 19 cases one cannot exclude that minor degrees of a similar personality change may have been overlooked for almost all our cases, though some showed improvement, remained institutionalized, and according to Ström-Olsen (1946) the personality changes often do not manifest themselves before the patient has returned to his normal environment. The variation in the location

through the whole of the white matter. (The case numbers of the 8 who died within seven weeks of operation are bracketed.) The variability in the plane of the cut which was demonstrated in a previous paper by Meyer and Beck (1945) was also apparent in this extended series of cases.

Each case, and often each hemisphere, presents as it were a separate human experiment. As most of our knowledge of the structural as well as functional organization of the frontal lobe and its connexions is based upon experimental work on animals, and human brains with concise lesions are rare, there is no need to emphasize the importance of investigating leucotomized brains from a comparative anatomical point of view. We have paid particular attention to the organization of the thalamo-frontal projections, especially of the dorsomedial nucleus; the fronto-pontine tract and, in particular, that prefronto-pontine part of the tract known as Arnold's bundle, which has not yet been investigated in the human brain; and the so-called long association tracts, whose anatomy and function are still shrouded in considerable obscurity. A detailed account of the anatomical findings in 10 fully investigated cases (extending the initial observations of Meyer and Beck, 1945) will be published shortly in *Brain* jointly with Mrs. Beck, to whom we are greatly indebted for much help in the preparation of this paper. We also at this point would like to express our gratitude to the many clinicians who have supplied us with the 27 brains and case-histories.

Turning to the clinico-pathological aspects of our material, the most arresting problem is that of personality changes which may follow lesions in the prefrontal region and which may throw light upon the wider problem of frontal lobe function. We shall confine our attention essentially to the question of the reality of the personality changes, and their possible substrate, and not concern ourselves with the various general theories of frontal lobe function. There is no need to define the term frontal lobe deficit syndrome after the many human and experimental contributions made on this subject, and the exhaustive reviews of the whole problem in the important monographs of Rylander (1939) and of Freeman and Watts (1942).

Of attempts at localization of mental activity, the most detailed and probably the most "atomistic" is that of Kleist (1934) who ascribes a special function to almost every Brodmann area: e.g. initiative to area 9; motor skill to area 10; constructive thinking to the middle frontal region (area 46); sentiment to the lateral orbital region (area 47); and personal and social ego to area 11. Kleist (1937) also stressed the relation of the prefrontal region to the hypothalamic-thalamic complex and the cingulate gyrus, a combination of centres which in modified form was presented by Papez (1937) as a cerebral mechanism of emotion and emotional expression. Yet another variant of Kleist's scheme is Spatz's (1937) concept of the "basal cortex", comprising the ventral parts of the frontal and temporal lobes, which he suggests may be concerned especially with emotional and personality integration. This last conception of the basal cortex as an entity has, from a functional organization point of view, recently been strengthened by the oscillographic work of McCulloch (1944) and his associates.

Criticisms of these concepts of frontal lobe localization have been made from several angles. The whole principle of localization of mental symptoms in the brain has been severely criticized by Lashley (1937), Masserman (1943), Golla (1946) and others. These criticisms are justified, we consider, only against the crudities of mechanistic localization. The concepts of localized and holistic function, as has been pointed out by Sherrington (1940), are not mutually exclusive: on the contrary, they are complementary.

There is also a possible criticism from the comparative anatomical angle. Recent work by von Bonin (1941) has shown that the volume of the frontal lobe is not

significantly larger in man than in the chimpanzee, in striking contrast to the temporal and parietal lobes which steadily enlarge from monkeys to man. This is supported by the oscillographic work by Kennard and McCulloch (1944). As a corollary to this it is interesting to remember that it is the theta rhythm, now believed to be the normal E.E.G. rhythm of the human temporo-parietal region, which is abnormal in conditions of immaturity, behaviour problems in children and aggressive psychopathy (Hill, 1945). Furthermore, the temporal lobe possesses the distinction of containing the only cerebral cortex devoid of thalamic projection (Walker, 1938). While these findings do not disprove the preoccupation of the frontal lobes with emotional and personality integration, they cast some doubt on the validity of using gross phylogenetic data in contending that the frontal lobes are man's greatest developmental achievement and therefore likely to be particularly concerned in his highest mental activities.

Serious criticism of the frontal lobe localization has come also from the clinical side. A specific personality change caused by lesions in the frontal lobes has never been generally accepted in this country. Walshe (1931) has recognized a frontal lobe syndrome, but one recalls an earlier joint meeting of this and the Neurological Section when only Gordon Holmes (1931) acknowledged the concept of personality changes due to frontal lobe tumours, whilst Kinnier Wilson, Mapother, Golla, Symonds and Worster-Drought more or less definitely rejected it.

The issue has been quite recently taken up by Hebb (1945) whose critical review on "Man's Frontal Lobes" seems to have aroused lively interest in this country. We agree with several of his critical points, and in particular that in all cases of bilateral pathological involvement or surgical removal of the frontal lobes there is the possibility that the pathological process itself may be more responsible for the mental changes than the loss of frontal lobe tissue. We disagree, however, with his evaluation of Hebb and Penfield's (1940) personal case as an instance of minimal, or even absent, deficit syndrome after bilateral lobectomy. The previous personality of an adolescent, even when known, cannot be taken as a reliable control guide to what his personality would have become after full uninterrupted maturation.

Hebb explicitly rejects the evidence from prefrontal leucotomy because of the uncertainty of the extent of the anatomical defect caused by the surgical lesions and the possibility of undetected pathological complications. He did not perceive that, provided it were possible to obtain a sufficient number of leucotomized brains from patients dying from intercurrent causes, and that clinical and psychological examinations before and after the operation were adequate, then all the conditions which he demands would be fulfilled, although of course it should not be forgotten that leucotomy is not identical with lobectomy. Of attempts at localization of mental activity, the most detailed and probably the most "atomistic" is that of Kleist (1934) who ascribes a special function to almost every Brodmann area: e.g. initiative to area 9; motor skill to area 10; constructive thinking to the middle frontal region (area 46); sentiment to the lateral orbital region (area 47); and personal and social ego to area 11. Kleist (1937) also stressed the relation of the prefrontal region to the hypothalamic-thalamic complex and the cingulate gyrus, a combination of centres which in modified form was presented by Papez (1937) as a cerebral mechanism of emotion and emotional expression. Yet another variant of Kleist's scheme is Spatz's (1937) concept of the "basal cortex", comprising the ventral parts of the frontal and temporal lobes, which he suggests may be concerned especially with emotional and personality integration. This last conception of the basal cortex as an entity has, from a functional organization point of view, recently been strengthened by the oscillographic work of McCulloch (1944) and his associates.

Criticisms of these concepts of frontal lobe localization have been made from several angles. The whole principle of localization of mental symptoms in the brain has been severely criticized by Lashley (1937), Masserman (1943), Golla (1946) and others. These criticisms are justified, we consider, only against the crudities of mechanistic localization. The concepts of localized and holistic function, as has been pointed out by Sherrington (1940), are not mutually exclusive: on the contrary, they are complementary.

There is also a possible criticism from the comparative anatomical angle. Recent work by von Bonin (1941) has shown that the volume of the frontal lobe is not

significantly larger in man than in the chimpanzee, in striking contrast to the temporal and parietal lobes which steadily enlarge from monkeys to man. This is supported by the oscillographic work by Kennard and McCulloch (1944). As a corollary to this it is interesting to remember that it is the theta rhythm, now believed to be the normal E.E.G. rhythm of the human temporo-parietal region, which is abnormal in conditions of immaturity, behaviour problems in children and aggressive psychopathy (Hill, 1945) . Furthermore, the temporal lobe possesses the distinction of containing the only cerebral cortex devoid of thalamic projection (Walker, 1938). While these findings do not disprove the preoccupation of the frontal lobes with emotional and personality integration, they cast some doubt on the validity of using gross phylogenetic data in contending that the frontal lobes are man's greatest developmental achievement and therefore likely to be particularly concerned in his highest mental activities.

Serious criticism of the frontal lobe localization has come also from the clinical side. A specific personality change caused by lesions in the frontal lobes has never been generally accepted in this country. Walshe (1931) has recognized a frontal lobe syndrome, but one recalls an earlier joint meeting of this and the Neurological Section when only Gordon Holmes (1931) acknowledged the concept of personality changes due to frontal lobe tumours, whilst Kinnier Wilson, Mapother, Golla, Symonds and Worster-Drought more or less definitely rejected it.

The issue has been quite recently taken up by Hebb (1945) whose critical review on "Man's Frontal Lobes" seems to have aroused lively interest in this country. We agree with several of his critical points, and in particular that in all cases of bilateral pathological involvement or surgical removal of the frontal lobes there is the possibility that the pathological process itself may be more responsible for the mental changes than the loss of frontal lobe tissue. We disagree, however, with his evaluation of Hebb and Penfield's (1940) personal case as an instance of minimal, or even absent, deficit syndrome after bilateral lobectomy. The previous personality of an adolescent, even when known, cannot be taken as a reliable control guide to what his personality would have become after full uninterrupted maturation.

Hebb explicitly rejects the evidence from prefrontal leucotomy because of the uncertainty of the extent of the anatomical defect caused by the surgical lesions and the possibility of undetected pathological complications. He did not perceive that, provided it were possible to obtain a sufficient number of leucotomized brains from patients dying from intercurrent causes, and that clinical and psychological examinations before and after the operation were adequate, then all the conditions which he demands would be fulfilled, although of course it should not be forgotten that leucotomy is not identical with lobectomy. Our material is as yet too limited and too unevenly investigated clinically, as well as pathologically, to fulfil these conditions; but even a provisional analysis gives some concrete idea of the potentialities of such an investigation, as the following brief survey may indicate.

In 6 out of the 19 patients who survived long enough for adequate clinical observation (from seven weeks to almost four years) symptoms of a frontal lobe deficit syndrome, such as euphoria, facetiousness, apathy, lack of initiative or overactivity, were recorded. In these cases we found little evidence of pathological changes different from those in the other cases, which might have caused the syndrome. In others of the 19 cases one cannot exclude that minor degrees of a similar personality change may have been overlooked for almost all our cases, though some showed improvement, remained institutionalized, and according to Ström-Olsen (1946) the personality changes often do not manifest themselves before the patient has returned to his normal environment. The variation in the location

through the whole of the white matter. (The case numbers of the 8 who died within seven weeks of operation are bracketed.) The variability in the plane of the cut which was demonstrated in a previous paper by Meyer and Beck (1945) was also apparent in this extended series of cases.

Each case, and often each hemisphere, presents as it were a separate human experiment. As most of our knowledge of the structural as well as functional organization of the frontal lobe and its connexions is based upon experimental work on animals, and human brains with concise lesions are rare, there is no need to emphasize the importance of investigating leucotomized brains from a comparative anatomical point of view. We have paid particular attention to the organization of the thalamo-frontal projections, especially of the dorsomedial nucleus; the fronto-pontine tract and, in particular, that prefronto-pontine part of the tract known as Arnold's bundle, which has not yet been investigated in the human brain; and the so-called long association tracts, whose anatomy and function are still shrouded in considerable obscurity. A detailed account of the anatomical findings in 10 fully investigated cases (extending the initial observations of Meyer and Beck, 1945) will be published shortly in *Brain* jointly with Mrs. Beck, to whom we are greatly indebted for much help in the preparation of this paper. We also at this point would like to express our gratitude to the many clinicians who have supplied us with the 27 brains and case-histories.

Turning to the clinico-pathological aspects of our material, the most arresting problem is that of personality changes which may follow lesions in the prefrontal region and which may throw light upon the wider problem of frontal lobe function. We shall confine our attention essentially to the question of the reality of the personality changes, and their possible substrate, and not concern ourselves with the various general theories of frontal lobe function. There is no need to define the term frontal lobe deficit syndrome after the many human and experimental contributions made on this subject, and the exhaustive reviews of the whole problem in the important monographs of Rylander (1939) and of Freeman and Watts (1942).

Of attempts at localization of mental activity, the most detailed and probably the most "atomistic" is that of Kleist (1934) who ascribes a special function to almost every Brodmann area: e.g. initiative to area 9; motor skill to area 10; constructive thinking to the middle frontal region (area 46); sentiment to the lateral orbital region (area 47); and personal and social ego to area 11. Kleist (1937) also stressed the relation of the prefrontal region to the hypothalamic-thalamic complex and the cingulate gyrus, a combination of centres which in modified form was presented by Papez (1937) as a cerebral mechanism of emotion and emotional expression. Yet another variant of Kleist's scheme is Spatz's (1937) concept of the "basal cortex", comprising the ventral parts of the frontal and temporal lobes, which he suggests may be concerned especially with emotional and personality integration. This last conception of the basal cortex as an entity has, from a functional organization point of view, recently been strengthened by the oscillographic work of McCulloch (1944) and his associates.

Criticisms of these concepts of frontal lobe localization have been made from several angles. The whole principle of localization of mental symptoms in the brain has been severely criticized by Lashley (1937), Masserman (1943), Golla (1946) and others. These criticisms are justified, we consider, only against the crudities of mechanistic localization. The concepts of localized and holistic function, as has been pointed out by Sherrington (1940), are not mutually exclusive: on the contrary, they are complementary.

There is also a possible criticism from the comparative anatomical angle. Recent work by von Bonin (1941) has shown that the volume of the frontal lobe is not

Dr. G. D. Greville and Dr. S. L. Last: *Leucotomy as an instrument of research. Electroencephalographic studies* [*Abridged*].—The material consisted of 35 cases, involving various psychiatric disorders. The operations were all performed by Mr. G. C. Knight, who employed in most of them Crombie's technique combined with that of Freeman and Watts. The E.E.G. was recorded whenever possible before leucotomy and again one day, ten days, three weeks, six weeks, three months, six months and one year after the operation: but on several occasions the state of the patient did not permit the examination, and on others the record had to be discarded on account of interfering artefacts due to the patient's restlessness and lack of co-operation.

Alpha activity (8 to 13 c/s).—Table I shows that the voltage of the alpha rhythm tends to increase after the operation. In some cases the voltage increases, in others it decreases and in a certain proportion it remains the same, but at one day after the operation more show an increase than a decrease, and this becomes more pronounced after three weeks. By "amount" of alpha activity (Table I) we mean the relative length of record occupied by this rhythm, e.g. whether it occurs continuously, or for half the time or only in short runs. The amount seems to increase after the operation, the tendency being most noticeable after ten days. The records of three cases studied by Davis (1941) show an increase in alpha voltage after leucotomy, and Cohn (1945) has remarked on an enhancement of alpha activity after the operation in Freeman and Watts's patients.

Table I.—Alpha Activity.
Number of records in which the voltage (or amount) was greater than, equal to, or less than that before the operation.

		Time after operation						
		1 day	10 days	3 weeks	6 weeks	3 months	6 months	1 year
Voltage	Greater	10	10	19	12	6	11	4
	Equal	3	6	4	3	2	1	0
	Less	6	6	0	2	2	1	1
Amount	Greater	8	10	10	7	4	7	1
	Equal	3	8	6	9	4	2	2
	Less	5	1	3	0	2	4	1

and extent of the cut may well account for some of the conflicting reports in the literature on the frequency, severity and variety of the personality change. In several of our cases indeed the damage to the prefrontal region was negligible.

A study of cases having wide variation of the position of the lesion in the prefrontal region also provides an opportunity of testing, for instance, Kleist's map (1934) of frontal lobe function, and kindred suggestions recently made by Dax and Radley-Smith (1946) for specific cuts: aggression to be alleviated by a dorsal, paranoid symptoms by a middle cut, and depression and tension by a cut nearer to the orbital region. In our material so far there may be a positive trend of correlation between improvement of depressive symptoms and orbital region involvement; but in the case exhibiting the severest degree of post-operative euphoria the orbital region was intact on both sides. For the other two types of case we have so far found no evidence of a positive correlation of improvement with the suggested cut. Further and more detailed observations are necessary, taking careful account as well of non-anatomical variables, such as previous personality and life-history.

Freeman and Watts (1944) observed during the operation that a previously responsive patient will drift into confusion when the medial segments of the prefrontal region are cut bilaterally. It is, therefore, interesting that the only 3 cases (among these 19) in which a post-operative confusion (of several days' duration) was noted were also the only ones with bilateral involvement of this medial segment (mainly of the Brodmann areas 32 and 24). Freeman and Watts's contention that this confusion is an essential factor in the mechanism of recovery is not borne out by these 3 cases or our material generally. It is uncertain what this symptom means in terms of physiology. Freeman and Watts (1944) favour involvement of the cingulate fasciculus rather than the cutting of callosal fibres as the operative factor. It will be remembered too that area 24 has been considered to be concerned with emotional expression (Papez, 1940; Smith, 1945) and that McCulloch (1944) regards area 32 as part of the "cingular belt" in which impulses coming from cortical suppressor bands are collected and where, thus, important cerebral activity appears to be concentrated.

In 2 of the cases in which the striatal region was involved in the cut severe restlessness and, in one case, rhythmic movements of the head, were mentioned in the case-notes. This might be of some significance in view of Mettler's (1945) similar observation in monkeys.

In 2 other patients developing after the operation marked vasomotor and trophic disturbances in the extremities area 6 was bilaterally involved. This recalls Kennard's (1935) earlier findings after ablation of the premotor area in monkeys, Knight's (1943) report of trophic disturbances following an unduly caudal leucotomy cut, and Ziegler and Osgood's (1945) report of such disturbances which they thought due to damage to areas 4, 6 and 8.

These few examples may suffice to demonstrate the importance of leucotomy as an instrument of research in neuropathological spheres. There are many other clinico-pathological correlations for which we are accumulating data, for instance, concerning post-operative epilepsy, speech defect, incontinence and disturbance of eye movements. They demonstrate also, we hope, the urgent need of a co-ordinated effort which must include on the one hand the fullest and most standardized clinical investigation in all directions before and after operation, and, on the other hand, effective arrangements for procuring the brain of patients dying from intercurrent illness. This will be a laborious research, but it should eventually furnish a decisive answer to many of our problems.

Theta activity (4 to 7 c/s).—This was widespread, with a tendency to frontal regions and no clear localization; the most common frequencies were 5 and 6 c/s. It occurred in a higher percentage of cases than delta activity and this percentage remained more constant with time. Table III shows that after the initial rise at ten days the frequency of occurrence of theta activity stayed constant at about 60 per cent., while that of delta dropped between three weeks and three months. This is scarcely in agreement with the statement of Cohn (1945) that theta activity gradually replaces delta in these cases. It should be pointed out, however, that while theta activity continued to appear in the later records, the amount in each record tended to diminish.

Following an operation which frequently either increases or decreases the aggressiveness of the patient it is natural to consider whether there is a connexion between aggressiveness and theta activity, since the latter is of frequent occurrence in aggressive psychopaths, as was first shown by Hill and Watterson (1942). We cannot, however, say that theta waves appeared particularly often when patients became aggressive, or rarely when they were apathetic or dull. This is scarcely surprising, however, since theta activity is by no means restricted to aggressive psychopathy, but occurs with subcortical tumours, epilepsy, &c., as well as in childhood and adolescence.

Discussion: *Causation of the delta activity.*—Delta activity is customarily regarded as arising from grey matter which has been damaged, as in head injuries or by a tumour, or is functioning at a reduced level, as in sleep, coma, hypoglycæmia or anoxia; that is, cortical cells the function or metabolism of which have been affected tend to discharge synchronously at a low frequency. In our cases we have seen that after the first few days, when the initial widespread disturbance has abated, the delta waves arise in general from the part of the cortex in front of the cut. It is possible that the delta activity then comes from those cell groups which have suffered direct damage from the operation, or more particularly through the cutting of their axons. On the other hand Meyer and Beck (1945) have shown that only comparatively few cells in the prefrontal cortex suffer permanent damage after leucotomy. We therefore suggest that it is the functional isolation of the prefrontal cortex from the rest of the brain which causes large groups of cells in the former to discharge synchronously. Bremer (1935) found that high-voltage activity in bursts results from deafferentation of the cortex in the *cerveau isolé* preparation of the cat. Kennard and Nims (1942), in experiments on monkeys, found an absence of abnormal waves when cortex only was removed, whereas slow activity appeared when the basal ganglia were partially destroyed. Here again, therefore, slow activity appeared when the cortex was deprived of the influence of some of the subcortical structures with which it is normally connected. The kind of problem we have been discussing may come nearer to solution when the brains of cases investigated with the E.E.G. can be examined histologically.

We should like to thank Dr. R. Ström-Olsen for his help and advice, and our collaborators, Miss J. E. H. Munson, Mr. P. St.John-Loe and Mr. D. Lee, for their patient work.

Dr. F. Reitman: Leucotomy as an instrument of research has been discussed from the neuropathological and electroencephalographic aspects. Physiological research is being conducted at Netherne Hospital in connexion with this subject. Experi-

TABLE II.—FAST ACTIVITY.

Number of records at different times with high, medium and low voltage fast activity, and with large, medium and small amounts of fast activity.

		Before operation	Time after operation						
			1 day	10 days	3 weeks	6 weeks	3 months	6 months	1 year
Voltage	High	6	3	2	3	3	2	2	0
	Medium	5	4	8	8	8	6	7	3
	Low	6	9	10	8	7	3	5	1
Amount	Large	10	8	4	6	7	2	5	2
	Medium	3	1	3	1	1	3	3	2
	Small	1	2	4	5	2	1	3	0

Fast activity (frequencies greater than 13 c/s).—The voltage of the fast activity tends to diminish after the operation, and there is some indication that the amount tends to decrease also (Table II).

The increase in alpha activity and decrease in fast activity may point to a greater ability to relax following the operation, and possibly the decrease in emotional tension displayed by many leucotomized patients is reflected in this alteration in the record. On the other hand, ability to relax may increase as the patient becomes used to the examination; for various reasons, however, we do not consider that this provides the full explanation.

Delta activity (frequencies less than 4 c/s).—Considerable technical difficulties were encountered here as the potentials arising from eye movements may be confused with frontal delta waves, and special methods had to be employed to distinguish eye movement artefacts from cortical potentials. Delta activity is fairly common after leucotomy, more than half our cases showing it at some time. If it is going to appear it usually appears by one day after the operation, certainly by ten days; thereafter it is seen in fewer cases, and in smaller amounts in individual records. At first delta activity may appear all over the cortex, but it soon becomes predominant in the frontal areas. At this time it may show some extension to central areas, but this gradually disappears, until after three weeks there is little delta activity which does not come from the front.

When an attempt at accurate location was made it was found, with dipolar recording, that the delta activity originated in front of the cut. Indeed, the indication was that it arose in the prefrontal areas. We are in agreement with Cohn (1945) who, with a monopolar derivation, found more delta activity the further forward he placed his electrodes. The delta waves were often strictly synchronous in the two hemispheres; and another feature was that whereas at first the waves appeared at random, after ten days the rhythm became more paroxysmal in nature.

One of the problems of delta activity is its correlation with age. Delta rhythms occur normally in children and disappear with increasing age. Abnormal rhythms are also dependent on age, since epilepsy and head injury show a diminishing tendency to produce slow activity in increasing age-groups. In our cases, however, there appears to be no correlation between delta activity and age. About 57 per cent. of the total cases developed delta activity; it was observed in 4 out of the 9 cases under 30 years, and in 16 out of the 26 over 30 years of age. It thus occurred with roughly the same frequency in the two age-groups; and a similar result is obtained if one considers patients above and below 35 years of age. There is some indication of a positive correlation between clinical improvement and the appearance of delta activity, but there are too few cases to allow a definite statement.

TABLE III.

Percentage of records, at different times, in which delta and theta activity was present.

	Before operation	Time after operation						
		1 day	10 days	3 weeks	6 weeks	3 months	6 months	1 year
Delta ..	0	57	57	36	15	17	19	0
Theta ..	15	64	85	58	58	64	65	60

On the other hand, the volume of gastric secretion under the influence of 1 mg. prostigmin (without test-meal) showed significant differences pre- and post-operatively, as seen on the histogram in fig. 1. The volume of gastric juice became considerably increased post-operatively, but it is noteworthy that no increase in the HCl production occurred.

In commenting on those results, it may be recalled that gastric activity has been described as consisting of three phases. First the cephalic phase, denoting psychogenic influences on the vagus. That the described findings are not of psychogenic nature is supported by the fact that they are independent of the therapeutic result of the operation.

Secondly, the so-called vagus phase: it is known that the vagus exerts its influence on the oxyntic cells, causing discharge of HCl, and that during the vagus phase of gastric activity, the gastric flow is increased; this is the so-called vagus juice. The chemical transmitters to the oxyntic cells are acetylcholine and histamine. Fulton pointed out that according to Messimy and Clifton, the ablation of the frontal association areas in monkeys (areas 9, 10, 11 and 12) causes increased gastric motility, and hyperactivity of the stomach, apparently as a result of increased autonomic activity, "The effects however tend to pass off with time." The findings which have been given are thus well in accordance with the experimental observations on animals. It is possible that part of the orbitofrontal cortex, where autonomic functions are located, becomes isolated by the low vertical incision. It is known that there is an overlapping of the sympathetic and parasympathetic systems in their cortical integration, and it would therefore seem to be not unlikely that the cholinergic activities described may be only a part of the autonomic changes which may later be found.

The third phase of gastric activity, induced by the vagus phase, is chemogenic, acetylcholine being the transmitter of the nervous impulses. It is of interest therefore that although prostigmin preserves the naturally liberated acetylcholine, no significant changes were found regarding the HCl content after prostigmin injection. It may be that although acetylcholine plays a lesser part in the production of HCl than does histamine, it still functions as a powerful activator of the vagus juice production. Further analysis of the third, or chemical phase of gastric activity is not within the scope of the present paper.

In a previous report it was demonstrated that in about two months after leucotomy an increased autonomic homeostasis seems to be established as seen by the patients' resistance to drugs which normally upset the autonomic balance. By this time the indirect cortico-hypothalamic degeneration is probably well established. Thus it may be that the transient autonomic changes described here have a cortical rather than a hypothalamic basis.

It is not justifiable to theorise on such a limited number of experimental observations, however encouraging the mathematical analyses may be. It would, however, seem that the results though as yet incomplete call for further investigations.

I wish to express my thanks to Dr. E. Cunningham Dax for his suggestions and criticisms; to Dr. F. Kraupl and Mr. W. A. Hulme for their technical help.

REITMAN, F. (1945) *J. ment. Sci.*, 91, 318.

Dr. M. B. Brody: The chief experimental finding from the psychological viewpoint is that prefrontal leucotomy does not impair capacity to perform mental tests. In the few papers which record mental test results unimpaired ability has been found mental physiology indicated and post-leucotomy autopsies confirmed the indirect connexions of the prefrontal lobes to the diencephalic centres. Furthermore, it has been established that the highest neural integration of autonomic functions lies in the cortex itself. Therefore it seems reasonable to suppose that partial severance of the thalamo-frontal radiation will induce alteration in autonomic balance. This report deals with changes in the parasympathetic functions as evidenced by the study of the influence of the vagus on gastric functions.

Nine cases have been selected for this report, all of which had pre-operative test meal curves within normal limits. All the cases underwent bilateral, low, vertical leucotomy, by the method which Dax and Radley-Smith (1946) reported to this Society. We believe that by this means fibres from the orbital surface of area 11 as well as from area 12 are amongst those severed.

Each case, when selected for operation had three test meals and each analysis was performed independently by two investigators. The average of the 3 test meal curves was taken as the "pre-operative curve" for each patient. It was hoped that by this method, any emotional factors which influenced the patients' test meal curves would be eliminated whilst the independent titration of two operators would remove reading errors. Similar procedures took place three, five, seven, and ten weeks after leucotomy.

A second group of investigations comprised the analysis of test meals taken under the influence of 1 mg. i.v. prostigmin, pre- and post-operatively, at about three, five, seven and ten weeks' intervals. In a third group of experiments gastric analysis was made after administering 1 mg. i.v. prostigmin alone. In each case the analyses were repeated and the results calculated from the mean of the readings.

The histogram (fig. 1) shows the pre- and post-operative test meal curves. After leucotomy the total acidity is slightly increased, the maximum of the total acidity is reached earlier than pre-operatively, and the emptying time is shortened. The significance of the differences between the pre- and post-operative curves was statistically significant. It should be added that the enumerated differences are already apparent three weeks post-operatively, and are increased at the five-weekly period but that the seven-week curves are less marked and the ten-week curves approximate uniformly to the pre-operative values. The total acidity under the influence of 1 mg. prostigmin if followed by a test meal did not show statistically significant changes.

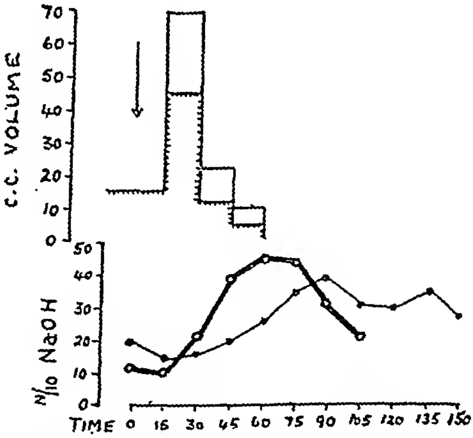

FIG. 1.—Above: Volume of gastric juice after 1 mg. i.v. prostigmin injected at arrow. Pre-operative, dotted line; post-operative, straight line. Below: Test meal curves. Pre-operative, thin line; post-operative, thick line. All amounts are calculated as averages (from 9 cases).

President—L. R. BROSTER, O.B.E., M.Ch.

[*November* 29, 1946.]

Chromophobe Adenoma in a Male Aged 15½ Years.—S. LEONARD SIMPSON, M.D., and A. DICKSON WRIGHT, M.S.

H. R., now aged 15½ years. At age 13½ while in Australia, suffered from headaches, ophthalmoplegia and later blindness in right eye, with optic atrophy. Left eye showed ptosis, partial optic atrophy and partial temporal hemianopia. Pituitary fossa was considerably enlarged (19 × 21 mm.). Puberty was said to have commenced at 13 but voice was not broken. General condition was one of weakness, apathy and adiposity.

Operation (A. D. W.) June 1945.—The adenoma had extended downwards into the sphenoidal fissure and posteriorly, elevating the optic chiasma. A large amount of necrotic tissue was removed. Histology showed chromophobe adenoma.

Recovery uneventful. A course of X-ray treatment was given because removal of tumour is often incomplete in such cases. Full movements returned to left eye and partial movements to right eye which, however, is still blind.

Result.—Improvement in degree of ophthalmoplegia, but patient weak, apathetic and bedridden, with no appetite and no volition. Testosterone advised (S. L. S.), 25 mg. daily by injections. Increased appetite and strength and sense of well-being. There was also an erotic effect. Up and about. A dramatic manifestation of the effect of testosterone on appetite, well-being, nitrogen retention and muscular strength.

A subcutaneous implantation of 400 mg. testosterone propionate is contemplated.

Chromophobe Adenoma in a Male Aged 67 Years.—S. LEONARD SIMPSON, M.D., and JULIAN TAYLOR, O.B.E., M.S.

In 1934 anæmia, loss of libido, and dyspnœa. In 1940, diminished vision right eye, and headache. Dr. F. W. Price suggested pituitary tumour and referred patient to Dr. F. M. R. Walshe, who diagnosed chromophobe adenoma. X-ray showed great enlargement of sella turcica.

Operation (J. T.) May 1940.—Right transfrontal approach. Intradural. Soft tumour sucked out. Histology showed chromophobe adenoma. One month later seen by S. L. S., complaining of weakness, sensitivity to cold, no libido. Facial hair and pubic hair slight, and axillary hair absent. Pallor. B.P. 90/60. Responded moderately at different periods to desoxycortone, thyroid, and pituitary adrenocorticotrophic hormone; and dramatically to methyl testosterone, 10 mg. under the tongue t.d.s. The patient wrote: "In the very first week there was an enormous improvement in my strength and vitality, and before the end of the first month I felt as I used to feel about twelve years ago before my health first began to deteriorate. I felt thoroughly well and strong, and able to do almost anything without fatigue."

After six weeks a maintenance dose was given of one 5 mg. tablet t.d.s. He was seen in October 1946 when libido, potency and secondary sexual characteristics had returned.

Pituitary Infantilism with Toxic Goitre.—A. W. SPENCE, M.D.

Single woman, aged 23, complaining of failure to grow, absence of periods, palpitations. Delayed growth particularly noticed at 14. Aged 16, given thyroid tablets because of primary amenorrhœa; these were stopped after six months on account of loss of weight, exophthalmos and palpitations. Condition practically unchanged. During past two years has had fortnightly injections of gestyl (pregnant mare's serum extract).

almost without exception. At Runwell Hospital, I tested patients before, and six weeks, four months, one year and two years after operation with a Vocabulary, Terman-Merrill, a modified Babcock, Porteus, Passalong, Kohs', Matrices, Shipley-Hartford, and a variety of sorting tests. Although I cannot present a detailed analysis of the data, I am satisfied that the results showed no impairment. In fact, I therefore abandoned my original project of testing at yearly intervals indefinitely. I next concentrated on investigations with tests of the Goldstein type. These were given at the same intervals as the intelligence tests, and again the results were negative.

This unexpected preservation of mental test ability raises the question: "What part does the prefrontal area play in the so-called higher intellectual processes?" Apparently none, or no indispensable part. On what areas of the brain then, do these functions depend? The most probable answer is on some kind of integrated activity of the cortex as a whole. But one must also consider whether areas other than the cortex are important, and in this connexion it has already been suggested that the true dementia of Pick's disease is associated with changes in the dorso-medial nucleus of the thalamus. The answer to such fundamental problems can be reached by studying prefrontal leucotomy not in isolation but as part of a study of all conditions involving organic brain changes, a study which calls for close co-operation between clinicians, neuro-histologists and psychologists using, as Dr. Meyer has said, a largely standardized technique of examination.

Amongst the patients were some who outside the test sessions showed lack of spontaneity—whose spontaneous ideation and activity did not reach the intellectual level and quality proved by the tests to be within their capacity. Clearly, the test situation, the act of setting a specific task to be done there and then under the examiner's eye, evokes some driving or urging power which is not spontaneously evoked, and is presumably non-cognitive in character. With this observation I wish to couple the clinical observation that after leucotomy, ideas which were formerly held with great emotion may remain unchanged after operation, but stripped of the emotion; and that this fading of the emotion often precedes fading of the ideas themselves.

These observations raise fundamental problems about the nature and genesis of ideation, and the relation of ideation to emotion. We need to know more of the relation of ideation to gnosis, praxis, and to those capacities which are impaired in aphasia, agraphia, alexia, acalculia, &c. Even the relation of ideation to perception is debatable, as may be realized by comparing the seemingly opposite views of Madison Bentley and Bartlett. Apropos the relation of ideation to emotion, Porteus and Kepner point out that although we are accustomed to talk of "ideas and their accompanying emotions", that is, we regard ideation as primary and the emotion as a consequent secondary feature, the truth may be that emotion is the primary state and ideation secondary, that is, that ideation is intellectualization of a primary emotional state. They renewed interest in this old problem because they found that subjects after leucotomy displayed certain changes in performing Porteus Mazes for which the explanation lies, they believe, in the emotional rather than cognitive field.

Pan-Hypopituitarism.—R. S. Bruce Pearson, D.M.

C. R., male, aged 36. First seen December 1944, complaining of breathlessness, lack of energy, hot flushes, spasmodic jerkings of the body. Symptoms present since October 1942 in Palestine when he had a severe pyrexial illness associated with headache, lasting a week. Then severely anæmic with low B.P.

On examination (October 1942).—Face and body hairless—skin soft and dry. Shaved once weekly. Features expressionless and voice toneless. Impotent. Some œdema of legs. Pale, but Hb. 88% (Haldane). Well covered. B.P. below 100 systolic.

Further investigations confirmed pan-hypopituitarism.

Since this time has received treatment with a variety of endocrine preparations with considerable subjective improvement, increased growth of hair and the return of normal sexual activity.

Case for Diagnosis. ? Diabetes Mellitus with Diabetes Insipidus.—A. C. Crooke, M.D.

Sylvia M., aged 10 years.

December 1940, aged 4 years, onset of diabetes mellitus. This has been well controlled by diet and insulin (20-32 units globin insulin daily).

She had not attended the clinic for five months but three months ago she developed excessive thirst and began passing large quantities of urine, although her mother, who tested the urine daily, said it was usually sugar-free and she occasionally had slight symptoms of hypoglycæmia. Mother tried to prevent her drinking, but she would run away to shops and ask for water. Otherwise very well; no relevant family history of previous illnesses.

On examination, 31.9.46.—No abnormal physical signs. Only slight glycosuria and no acetone.

Admitted to hospital: Slight pyrexia which has since persisted. Catheter specimen of urine: Coliform organisms cultured, no pus, no other cause for pyrexia found. X-rays chest and skull normal. Began to show marked glycosuria; insulin increased progressively to 100 units soluble in 3 divided doses daily. Glycosuria now fairly well controlled again; still frequency of micturition (15-25 times day, 3-8 times night); 5-11 pints in twenty-four hours.

Basophilism Treated Unsuccessfully with Massive Doses of Oestrogens and Deep X-ray Therapy, but Cured by Radon Seeds Inserted into the Sella Turcica.—A. C. Crooke, M.D.

Maud F., married, aged 30, admitted to London Hospital 26.5.40. Her only child had been born eight months previously. Two months later weight began to increase rapidly and broad purple striæ atrophicæ appeared on abdomen. Excess of hair developed on upper lip. Face became bloated and bluish-red, skin greasy. Periods became irregular and finally ceased. Moderate cervicodorsal kyphosis.

When first seen B.P. 150/70; subsequently lower. Diabetic sugar tolerance curve. Deep X-ray treatment by Dr. Jupe, of 1,000 r in twenty-two days. Condition deteriorating rapidly; transferred to Mr. Northfield. 14.10.40: Two radon seeds, each of 1·5 millicuries, inserted into pituitary gland. Within nine days face less bloated, bluish tinge disappeared. Abdominal striæ pale pink.

After discharge complained of fatigue and great muscular weakness. Lost 3½ st. in weight. Subsequently gained 1 st.

It was considered that she was suffering from a degree of pituitary insufficiency, but she gradually recovered and all her symptoms disappeared, except that her menstruation has been very irregular with long periods of amenorrhœa.

Father 5 ft. 4 in. Mother 5 ft. Heights of four adult brothers range from 5 ft. 5 in. to 5 ft. 10 in.; of three adult sisters from 5 ft. 2 in. to 5 ft. 6 in.

On examination.—Height 4 ft. 6 in., weight 5 st. 9 lb. Appears ten years younger than her age. Co-operative, composed, intelligent. Infantile configuration and development: mild oxycephaly, well covered, not obese, breasts poorly developed, pigmented nipples, no axillary hair, pubic hair scanty. Infantile vagina, hyperextensibility of joints and mild pes planus. Moderate exophthalmos with lid retraction and slight lid lag. Slight tremor of hands. Thyroid moderately enlarged. Heart normal; pulse (day) 120-140, (night) 80-90. B.P. 165/95. E.C.G. sinus tachycardia. Hb. 90%. W.B.C. 5,000. B.M.R. + 33%. Blood cholesterol 112 mg. per 100 c.c. X-rays: Pituitary fossa 9 × 6 mm. Wrists: Non-fusion of epiphyses and decalcification. Urinary excretion of 17-ketosteroids: 5 mg. in twenty-four hours.

Dr. V. C. Medvei: The case presented certain difficulties. My Chief, Dr. Spence, encouraged me to offer an alternative attempt at explanation.

(1) The hypopituitarism is not quite typical; the blood-pressure has always been rather high.

(2) The exophthalmos became noticeable after thyroid administration, but it may have begun two years before that.

(3) The condition has not changed for the last two and a half years, and the pulse-rate comes down to 72 while she is asleep.

(4) X-ray evidence of a delayed ossification is not usual in pituitary dwarfism beyond the age of 21. In thyroid disorders delayed ossification is significant for juvenile myxœdema.

(5) A deformity of the skull is present. Schueller pointed out combination between acrocephaly, chondrodystrophy and other forms of dwarfism. J. Bauer found a combination of acrocephaly and exophthalmos often concurrent. Thomas described a girl of 1½ years with acrocephaly, enlarged sella and exophthalmos. In 1924 a young girl of 15 was referred to J. Bauer with exophthalmos and signs of hyperthyroidism as an exophthalmic goitre. She belonged to a similar group that was first described by Crouzon in 1912 as a cranio-facial dysostosis.

Long-standing Hypopituitarism with Recent Signs Suggesting Either Chromophilic Adenoma or Suprasellar Tumour.—H. S. Le Marquand, M.D.

Female patient, aged 28 years.

History.—Birth-weight 7½ lb. Developed normally until the age of 8 years when diabetes insipidus occurred. This cleared spontaneously at 11 years.

November 1938: First seen, aged 20. Measurements: Head 20·5 in. (= age of 6½ years); height 55·5 in. (= age of 11 years); weight 75 lb. (= age of 11½ years).

X-rays: Epiphyseal development retarded by two years. Pituitary fossa at upper limit of normal size. Small stature and development. Fine wrinkled skin, undeveloped breasts, amenorrhœa.

Diagnosis: Hypopituitarism.

1942: When examined by gynæcologist under anæsthesia all that could be felt of internal genital organs was a minute cervix. During eight years of observation has been treated with thyroid gland, various pituitary preparations and with œstradiol. Menstrual bleeding while under treatment with œstradiol. Has grown ¾ in. and put on 15 lb. Mammary glands have developed. Pubic hair present. June 1946: Aged 28. Complained of loss of vision of right eye. Mr. Cashell reported: "Slight constriction of R. field of vision, slight pallor of R. disc." Vision L. and R. 6/6. Dr. Cave reported: "Pituitary fossa enlarged, posterior clinoid process thin." September 1946: Course of deep X-ray therapy to pituitary gland. October 1946: Mr. Cashell reports: "There is optic atrophy of the R. disc, the loss of central fixation is due to a R. hemianopic scotoma which has affected the macular bundle. Lesion is increasing and there is a suggestion of a L. temporal defect. Vision R. 6/60. L. 6/6."

Pan-Hypopituitarism.—R. S. Bruce Pearson, D.M.

C. R., male, aged 36. First seen December 1944, complaining of breathlessness, lack of energy, hot flushes, spasmodic jerkings of the body. Symptoms present since October 1942 in Palestine when he had a severe pyrexial illness associated with headache, lasting a week. Then severely anæmic with low B.P.

On examination (October 1942).—Face and body hairless—skin soft and dry. Shaved once weekly. Features expressionless and voice toneless. Impotent. Some œdema of legs. Pale, but Hb. 88% (Haldane). Well covered. B.P. below 100 systolic.

Further investigations confirmed pan-hypopituitarism.

Since this time has received treatment with a variety of endocrine preparations with considerable subjective improvement, increased growth of hair and the return of normal sexual activity.

Primary Hyperplasia of the Parathyroids in a Boy Aged 8 Years.—N. F. ELLIOTT BURROWS, B.M., for W. G. WYLLIE, F.R.C.P.

Three months preceding admission, insidious onset of anorexia, increasing polydipsia with enuresis, occasional vomits and frequent pains in head, abdomen and behind knees. Progressive muscular weakness. Attack of tonsillitis at onset. Measles only other illness. Parents and two siblings healthy.

On examination.—Extreme lethargy and recent weight loss; subsequently nuchal stiffness and frontal headache. Blood-count: R.B.C. 5,280,000; Hb. 85%; C.I. 0·81; W.B.C. 8,900 (polys. 50%). C.S.F. pressure 70 mm. Urine: Acid, Alb. 15 mg.%. Blood urea 35 mg.%. 1 : 1,000 Mantoux very strongly positive. B.P. 95/65.

Course in hospital.—During next five months symptoms continued unabated. No evidence of active Tb. found. No benefit from posterior pituitary extract injection. Intravenous pyelography attempted on three occasions but renal concentration was lacking. Routine agglutination reactions negative. E.S.R. remained around 60 mm. in one hour. ? tuberculoma in floor of fourth ventricle. Normal ventriculogram performed by Mr. Wylie McKissock.

Attention was drawn to skeletal system by appearance of rarefaction in necks of femurs and by necrotic nature of cranial bur holes. Extreme osteoporosis of skull. Urine: Heavy precipitate with Sulkowitch reagent. Blood: Serum calcium 18·8 mg.%. Inorganic phosphorus 2·8 mg.%. Alkaline serum phosphatase 93 units.

Operation (C. Donald).—Exploration of parathyroids. Tumour removed, the size of large hazel nut, purple in colour, inferior to thyroid capsule beneath sternal notch. Histologically diffuse hyperplasia, without evidence of adenomatous arrangement.

Progress.—Immediate amelioration of many symptoms. Fluid intake dropped to 25 oz. daily, no further enuresis. Blood Ca fell in six days to 6·5 mg.%. Alkaline serum phosphatase continued greatly raised. No tetany; level restored by high Ca intake with 10,000 units vitamin D daily. Weight gain of over 4 lb. in less than three weeks; improvement in muscle tone. Progress continuous. Bones show marked improvement. Three weeks after operation blood chemistry revealed: Serum Ca 9·4, Inorganic P. 3·3 mg.%. Alk. S.P. 62 units. On 8.10.46: Serum Ca 10·9, Inorganic P. 3·4 mg.%. Alk. S.P. 14 units.

Precocious Puberty of ? Suprarenal Origin.—N. F. ELLIOTT BURROWS, B.M., for W. G. WYLLIE, F.R.C.P.

John A., aged 5¾ years. Normal birth and babyhood until eighteen months when his genitalia were thought large for his age. Since then he has grown excessively: adult muscular build, pubic hair, enlarged penis, but normal sized testicles.

17-ketosteroids, 20.9.46: 18·4 mg. 4.10.46: 11·4 mg. per day.

23.10.46. Laparotomy by Mr. Twistington Higgins. Left kidney and suprarenal felt normal, right kidney outline nobbly towards upper pole. 6.11.46: Second operation. Right kidney incision with rib resection. Suprarenal enlarged but no localized tumour, the enlargement was diffuse, extending to diaphragm and was separated with difficulty. Suprarenal partly removed in two pieces.

17-ketosteroids. 18.11.46: 5·2 mg. per day. Bone age of boy of 13 years. Skull X-ray normal.

Histological report [Dr. Martin Bodian].—(1) Main piece of gland 3·7 g., (2) subsidiary piece 0·9 g. containing a little yellow nodule.

(1) Normal zonal architecture of cortex with hardly any medullary tissue present. Vine's Ponceau fuchsin reaction negative. No mitotic or multinucleated cells.

(2) Nodule consists of cortical tissue without orderly zonal arrangement and has larger cells than main gland. Histological appearances do not indicate neoplasm or hyperplasia.

Section of Pædiatrics

President—DENIS BROWNE, F.R.C.S.

[*October* 25, 1946]

Kala-Azar in Infancy

By Professor J. E. DEBONO (*Malta*)

ALTHOUGH indigenous leishmaniasis does not occur in England, cases might be, and in fact are, imported from endemic areas. Their very rarity make diagnosis more difficult unless the possibility of the disease and its main features are kept in mind. There is no essential difference between infantile and adult leishmaniasis. The parasite and the pathology are the same and it is more exact to speak of leishmaniasis in infancy. Infection in infants is associated with canine leishmaniasis and is most prevalent in the Mediterranean area. In China older children are affected and in India and the Sudan, adults are attacked. There is no hard and fast rule, however, and it is quite possible for a baby to acquire the disease in an area where the adult form is prevalent. It is important to remember that leishmaniasis is not necessarily a tropical disease and that in Europe itself it could occur in any place south of the latitude of Paris.

"Infancy" in connexion with kala-azar is not to be regarded in its strict sense of the first year of life. In Malta the age distribution of the last 200 cases was as follows:

0 to 1 year ..	10	4 to 5 years ..	20
1 to 2 years ..	76	5 to 6 years ..	8
2 to 3 years ..	55	6 to 7 years ..	2
3 to 4 years ..	26	7 to 8 years ..	3

The youngest patient was 4 months old.

The basic pathological lesion is a marked and universal proliferation of the reticulo-endothelial system. On inoculation by the phlebotomus the flagellate leishmaniæ penetrate reticulo-endothelial cells in the immediate neighbourhood and change into the spherical form known as the "Leishman-Donovan Body" (L.D.B.). Here they multiply and pass on to other R.-E. cells via the minute protoplasmic processes which connect these cells together. In tropical sore the infection remains localized, in visceral leishmaniasis the parasites are disseminated throughout the whole R.-E. system. Probably dissemination occurs through the detachment of infected endothelial cells and their carriage by the circulation to the spleen, liver, bone-marrow, glands and intestines.

Under the stimulus of parasitic invasion both the cells and the reticulum proliferate. The spleen enlarges to a size only rivalled by myelocytic leukæmia; the Malpighian bodies disappear. In the liver the proliferation of Kupffer's cells produce atrophy of the parenchyma. The superficial lymph glands are only moderately enlarged and rarely give rise to diagnostic difficulties. The enlargement is more marked in the tracheo-bronchial and mesenteric groups, but this is probably the result of repeated secondary infections. In the intestines a sheet of infected cells sometimes lines the subserous membrane. Ulcers may form from time to time in the colon and give rise to dysenteric symptoms with passage of blood and mucus.

The most important changes take place in the bone-marrow. The hæmopoietic elements are encroached upon and crowded out by the infected and proliferated R.-E. tissue, producing a condition analogous to aplastic anæmia. The anæmia of leishmaniasis is normocytic and orthochromic. There is no evidence of hæmolysis and no reticulocytosis. The erythrocytes are not injured in any way but their production is seriously interfered with. In ordinary cases the average red count is

Primary Hyperplasia of the Parathyroids in a Boy Aged 8 Years.—N. F. Elliott Burrows, B.M., for W. G. Wyllie, F.R.C.P.

Inorganic P. 3·3 mg.%. Alk. S.P. 62 units. On 8.10.46: Serum Ca 10·9. Inorganic P. 3·4 mg.%. Alk. S.P. 14 units.

Precocious Puberty of ? Suprarenal Origin.—N. F. Elliott Burrows, B.M., for W. G. Wyllie, F.R.C.P.

John A., aged 5¾ years. Normal birth and babyhood until eighteen months when his genitalia were thought large for his age. Since then he has grown excessively: adult muscular build, pubic hair, enlarged penis, but normal sized testicles.

17-ketosteroids, 20.9.46: 18·4 mg. 4.10.46: 11·4 mg. per day.

23.10.46. Laparotomy by Mr. Twistington Higgins. Left kidney and suprarenal felt normal, right kidney outline nobbly towards upper pole. 6.11.46: Second operation. Right kidney incision with rib resection. Suprarenal enlarged but no localized tumour, the enlargement was diffuse, extending to diaphragm and was separated with difficulty. Suprarenal partly removed in two pieces.

17-ketosteroids, 18.11.46: 5·2 mg. per day. Bone age of boy of 13 years. Skull X-ray normal.

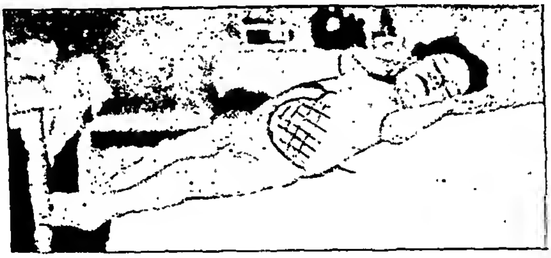
Histological report [Dr. Martin Bodian].—(1) Main piece of gland 3·7 g., (2) subsidiary piece 0·9 g. containing a little yellow nodule.

(1) Normal zonal architecture of cortex with hardly any medullary tissue present. Vine's Ponceau fuchsin reaction negative. No mitotic or multinucleated cells.

(2) Nodule consists of cortical tissue without orderly zonal arrangement and has larger cells than main gland. Histological appearances do not indicate neoplasm or hyperplasia.

temperature chart. The fever in leishmaniasis is made up of a number of short sharp rises or *accesses* of temperature in the twenty-four hours. There is one about 11 a.m., perhaps another rise in the evening and almost invariably a rise at night, followed by sweating in the early hours of the morning. The double and even triple rise of temperature is very suggestive. In its absence the diagnosis must be made by exclusion and confirmed if possible by culture of the parasite from the blood.

In the fully-developed case diagnosis is easier. The appearance is often characteristic. The child is thin, emaciated, looks miserable and suffers from general hypotonia. The abdomen is swollen and shows a marked protuberance either in the left hypochondrium or in the hypogastrium when the child stands up. The facies varies. In dark children there is an almost pathognomonic deep greenish pigmentation of the face and exposed parts. Fair children develop a marked pallor, which together with the slight generalized œdema suggests subacute nephritis (*see* fig.).



The spleen at this stage is often enormously enlarged reaching down into the left iliac fossa and crossing over to the right half of the abdomen. It is firm but not hard and there is no tenderness unless there has been recent infarction. With considerable enlargement and hypotonic muscles, ptosis of the spleen is almost invariable, hence the pendulous and protuberant abdomen.

The disease has to be differentiated from the long list of conditions which produce splenomegaly in children. Careful clinical examination and repeated examination of the blood enable one to eliminate the majority of these including malaria. In young babies the possibility of congenital syphilis has to be considered. In Malta the diagnosis is complicated by the frequency of undulant fever, but in this disease the spleen never attains the size it reaches in kala-azar.

The decisive test—to be carried out in all cases before treatment is started—is the demonstration of the leishmaniæ. This is best done by splenic puncture. Many tests and procedures have been devised to avoid the risks of this supposedly dangerous operation, but none could compare with it as regards reliability. The aldehyde, the antimony and Ray's tests are not usually positive before the fourth month and they may be positive in other conditions. The complement-fixation test is still in its infancy. Blood culture requires a meticulous technique and at best is positive in only 70% of the cases. Bone-marrow, liver and gland puncture have been suggested and used as alternatives. Of these tibial puncture is probably the best, but in my opinion it is more dangerous and certainly more painful than splenic puncture. The most important point, however, is that it is often negative when the splenic juice is teeming with parasites.

Splenic puncture is simple, and when performed with proper precautions is practically devoid of danger. In my experience extending over 2,000 cases there has

2,500,000 per c.mm., but in severe and advanced cases it may be as low as 1,000,000 per c.mm. The myelocytic tissue suffers to an even greater extent and leucopenia is a prominent feature of leishmaniasis. In advanced cases the leucocytes are often reduced to 2,000 per c.mm. or even less. The granulocytes are chiefly affected and a condition tantamount to agranulocytosis may occur. This neutropenia is no doubt responsible for the great liability to secondary infections and the occurrence of cancrum oris. There is a relative as well as an absolute monocytosis. The megakaryocytes are reduced to vanishing point and in the circulation the platelets may fall to 100,000 or under. This thrombocytopenia results in a tendency to hæmorrhages, purpura and ecchymoses.

The plasma shows marked alterations of which the most important is a fall in the albumen and a rise in the globulin fraction. The changes in the plasma are the basis of a number of diagnostic tests and produce an accelerated sedimentation rate. The fall in the albumen level together with the low hæmoglobin are responsible for the œdema commonly seen in advanced cases.

The clinical picture is a reflection of the underlying pathology. The incubation period is long, corresponding to the slow invasion and dissemination. It is usually stated to be between three and four months, but longer periods occur. If one added the latent period between the first symptoms and the full development of the disease eighteen to twenty-four months might easily elapse, and the possibility of such a prolonged incubation has to be considered in investigating the history. The onset of kala-azar is usually insidious with slight irregular fever and a gradual loss of appetite, colour, weight and energy. As these symptoms occur at a time of life when trivial complaints are common, they are often neglected and it may be months before the real nature of the disease is recognized. Occasionally, and more frequently in children under 2 years, the onset is acute with hyperpyrexia, chills and vomiting. The initial febrile period lasts two to six weeks and constitutes the first "wave". This is followed by an intermission—the so-called "latent period" which lasts another two to six weeks but can be much longer. Thereafter the fever rises again and the spleen begins to enlarge and continues to do so at the rate of two to three fingerbreadths per month.

Untreated leishmaniasis in infants is invariably fatal. The course could be acute, subacute or chronic. Acute leishmaniasis is commoner in young babies. It is characterized by a violent onset, high continuous fever, and rapid but moderate enlargement of the spleen. There is no latent period and death occurs in three to four months. The majority of cases in Malta run a subacute course lasting six to eighteen months: the trend is progressively downwards with persistent fever, increasing splenomegaly and progressive anæmia and cachexia. It is punctuated by alternating attacks of diarrhœa and bronchitis. The disease may be cut short by a fatal attack of bronchopneumonia or by the development of cancrum oris. Otherwise the child dies of marasmus and exhaustion. Sudden and unexpected death sometimes occurs even in children, who are apparently improving under treatment. It is heralded by hyperpyrexia, vomiting, rapid pulse, intense dyspnœa, cyanosis and extensive hæmorrhages under the skin. The picture is reminiscent of acute suprarenal hæmorrhage.

In older children the disease sometimes runs a chronic course lasting for two or more years with periods of almost total recovery, in which the only symptom is the splenomegaly. According to some Continental authors many of these cases recover spontaneously.

The diagnosis of leishmaniasis before the spleen is definitely enlarged is very difficult and often is only made retrospectively. At this stage leishmaniasis presents itself as a fever of unknown origin The leucopenia is helpful but the most important clue is afforded by an analysis of the temperature by means of a two- or four-hourly kala-azar in infants would have served equally well for that disease when seen in India in infants and it would seem, therefore, that in either case we deal with the same clinical entity.

As a possible explanation of this difference in the two areas I would like to advance a tentative hypothesis in the hope that it may raise some discussion among those familiar with this disease. We know that in the Mediterranean area kala-azar is essentially a disease of dogs and that man (infants and young children) is more or less accidentally infected, whereas in India the disease in dogs is at present unknown. In infected dogs the skin often harbours the parasite in very large numbers and is a rich source of infection for the carrier sandflies.

The very considerable percentage of infected dogs in close association with children in the Mediterranean area would result in most of the children in such areas being repeatedly infected with small doses of leishmania parasites from sandflies which had previously fed on the dogs. In some of these children, owing to a large dose of parasites on some occasion, or for some other reason, the disease might manifest itself as a frank case of kala-azar. In the others the repeated dosage with parasites might build up an immunity which could be maintained by a low grade and inapparent infection in the skin so that in later life they would be immune. Such a train of events would be a possible explanation of the comparative rarity of the disease in adults. In India, on the other hand, where no animal reservoir is known this same immunity would not be built up and therefore older children and adults would be fully susceptiole to infection. Corroboration is lent to this theory by the fact that in the Mediterranean area adults coming from non-endemic areas, such as troops from Great Britain, appeared to be much more susceptible than adults of the local population.

With regard to diagnosis by spleen puncture I was glad to hear that Professor Debono finds spleen puncture the best and most reliable method of diagnosis and considers it much superior to sternal puncture. This has been our experience in India and I am glad to have it confirmed by Professor Debono from Malta because, for some reason, there is the greatest reluctance in this country in employing spleen puncture on account of the supposed risky nature of the operation. In actual fact, as proved on thousands of cases in India, the operation, properly performed, carries little risk and is the most effective means of diagnosis in this disease.

Three points occur to me for discussion: In certain villages in Greece a considerable number of cases of kala-azar in infants have been of a hæmorrhagic type; that is to say, the skin of these infants has shown small hæmorrhages almost covering the body whilst in neighbouring villages the disease has been present without this phenomenon.

Secondly, statements have been made by some workers that the pentavalent antimony preparations are less effective in Mediterranean kala-azar than in Indian as evidenced by the greater quantities of those drugs required for cure and the marked tendency to relapse.

Lastly, has Professor Debono come across any cases of the condition which has been described in India under the name Dermal Leishmanoid?

Professor Debono (in reply): Colonel Shortt's theory regarding the different age incidence in Malta and India is very attractive. The only difficulty is that mild and abortive forms have not been met with in children. We have not seen any special hæmorrhagic type of kala-azar. Petechiæ and hæmorrhages occur in advanced and neglected cases. In spite of a check-up on all our old cases, going back to a period of ten years, no signs of anything resembling Dermal Leishmanoid were noted.

[*November* 22, 1946]

Thyrotoxicosis in a Child Aged 2 Years 9 Months.—GERALD SLOT, M.D.

Bessie E. Six months ago parents began to notice that the child's eyes were becoming more prominent, the condition becoming gradually more obvious since then. She has been otherwise normal except that she has had some diarrhœa and has not been gaining weight.

Previous history.—Pneumonia when aged 1 year.

Family history.—No family history of goitre. Both parents healthy. One other child, aged 5 months, appears normal.

On examination.—Normal intelligence. Marked bilateral exophthalmos. All eye signs for exophthalmos. Diffuse enlargement of thyroid gland, smooth surface. Right lobe larger than left. Tremor of fingers on stretching out arms. Sleeping pulse average 120. Heart: within normal limits, heart sounds normal.

Investigations.—X-ray skull: No gross abnormality, pituitary fossa normal. X-ray chest normal, no retrosternal goitre. Blood cholesterol 135 mg. per 100 c.c. W.R. and Khan negative. Blood-count: Hb. 88%; W.B.C. 6,000; normal differential. E.C.G. shows tachycardia. B.M.R. not possible owing to patient's age. Rough been two fatalities—one in a child suffering from leukæmia and the other in a moribund patient.

The specific treatment of infantile leishmaniasis was introduced by Caronia of Catania in 1914. The sodium-antimony tartrate used originally has been substituted by pentavalent organic antimony compounds, which are equally effective but less toxic. There are a large number of these preparations each with its own advocates and enthusiasts, but I think success depends more on the scheme of treatment and on attention to details than upon the drug itself. Before the war Neostibosan was used, but since 1940 Neostam—the only preparation that could be obtained at the time—has been employed with very satisfactory results. In the last series of 200 cases there has been 3 deaths and 7 relapses, a result which compares well with those obtained in other clinics. Stilbamidine, a different kind of preparation, which has proved very effective in the resistant Sudan kala-azar was ineffective when tried in Malta, and its use had to be abandoned on account of the severe toxic reactions.

Most of the patients in Malta were treated as out-patients. The injections were given three times a week on alternate days. It was found that the intensive treatment by daily injections was not suitable for children. It upset them too much and was often followed by relapses. The injections were always given intravenously, in young infants in the jugular vein. This presented no special difficulty. Absorption after intramuscular injection was often irregular and in many cases the drug failed to reach a sufficient concentration in those situations where it was needed. The result was the development of antimony fastness on the part of the leishmaniæ, with persistence of the infection or an early relapse. When intramuscular Neostibosan was the standard treatment the relapse rate was as high as 20%.

It was impossible to calculate the dose according to the weight as young children required proportionately more than older ones. The following plan was therefore adopted. The initial dose was 0·05 gramme. This was increased by another 0·05 gramme (or 0·025 gramme in the case of infants under 1 year and debilitated patients) until the limit of tolerance, shown by immediate vomiting, was reached. The average dose was 0·10 gramme to 0·15 gramme in babies under 1 year, 0·2 gramme to 0·25 gramme in those under 2 years and 0·3 gramme in older children. The treatment consisted of 16 injections. The full course was given even if improvement was immediate. On the other hand no attempt was made to exceed this number of injections even if the spleen remained large. In most cases the splenomegaly receded without further treatment. If after two months the spleen was still large and L.D.B.s were still present, another course, with a slightly higher dosage was given. Increasing the number of injections or starting a new course before the end of two months was followed in most cases by signs of antimony poisoning.

Adjuvant treatment is of the greatest importance. Hospitalization is avoided as much as possible to avoid secondary infections. Iron and vitamin supplements were given in all our cases. Strict oral hygiene was insisted upon to avoid the development of cancrum oris. Blood transfusions were given whenever the hæmoglobin fell under 40%. Penicillin has no specific effect on the leishmaniasis itself, but it has proved invaluable in the treatment of intercurrent bronchopneumonia and together with blood transfusion was life-saving in the case of cancrum oris.

Colonel H. E. Shortt, I.M.S.: I would like to draw attention to the word "infancy" in the title of Professor Debono's paper. Why should kala-azar be so predominantly a disease of infants in the Mediterranean area as compared with kala-azar in the East, and especially in India, where the disease is relatively uncommon in infants? Thus in India the percentage of cases in children under 1 year old is 0·06 whereas in the Mediterranean area 10 to 11% of cases are in children at the breast and over 60% of cases are in children up to 2 years old. On the other hand Indian kala-azar is a disease of older children and young adults, while the Mediterranean form is comparatively rare among adults. In spite of these differences the clinical picture drawn by Professor Debono of kala-azar in infants would have served equally well for that disease when seen in India in infants and it would seem, therefore, that in either case we deal with the same clinical entity.

As a possible explanation of this difference in the two areas I would like to advance a tentative hypothesis in the hope that it may raise some discussion among those familiar with this disease. We know that in the Mediterranean area kala-azar is essentially a disease of dogs and that man (infants and young children) is more or less accidentally infected, whereas in India the disease in dogs is at present unknown. In infected dogs the skin often harbours the parasite in very large numbers and is a rich source of infection for the carrier sandflies.

The very considerable percentage of infected dogs in close association with children in the Mediterranean area would result in most of the children in such areas being repeatedly infected with small doses of leishmania parasites from sandflies which had previously fed on the dogs. In some of these children, owing to a large dose of parasites on some occasion, or for some other reason, the disease might manifest itself as a frank case of kala-azar. In the others the repeated dosage with parasites might build up an immunity which could be maintained by a low grade and inapparent infection in the skin so that in later life they would be immune. Such a train of events would be a possible explanation of the comparative rarity of the disease in adults. In India, on the other hand, where no animal reservoir is known this same immunity would not be built up and therefore older children and adults would be fully susceptible to infection. Corroboration is lent to this theory by the fact that in the Mediterranean area adults coming from non-endemic areas, such as troops from Great Britain, appeared to be much more susceptible than adults of the local population.

With regard to diagnosis by spleen puncture I was glad to hear that Professor Debono finds spleen puncture the best and most reliable method of diagnosis and considers it much superior to sternal puncture. This has been our experience in India and I am glad to have it confirmed by Professor Debono from Malta because, for some reason, there is the greatest reluctance in this country in employing spleen puncture on account of the supposed risky nature of the operation. In actual fact, as proved on thousands of cases in India, the operation, properly performed, carries little risk and is the most effective means of diagnosis in this disease.

Three points occur to me for discussion: In certain villages in Greece a considerable number of cases of kala-azar in infants have been of a hæmorrhagic type; that is to say, the skin of these infants has shown small hæmorrhages almost covering the body whilst in neighbouring villages the disease has been present without this phenomenon.

Lastly, has Professor Debono come across any cases of the condition which has been described in India under the name Dermal Leishmanoid?

Professor Debono (in reply): Colonel Shortt's theory regarding the different age incidence in Malta and India is very attractive. The only difficulty is that mild and abortive forms have not been met with in children. We have not seen any special hæmorrhagic type of kala-azar. Petechiæ and hæmorrhages occur in advanced and neglected cases. In spite of a check-up on all our old cases, going back to a period of ten years, no signs of anything resembling Dermal Leishmanoid were noted.

[*November* 22, 1946]

Thyrotoxicosis in a Child Aged 2 Years 9 Months.—GERALD SLOT, M.D.

Bessie E. Six months ago parents began to notice that the child's eyes were becoming more prominent, the condition becoming gradually more obvious since then. She has been otherwise normal except that she has had some diarrhœa and has not been gaining weight.

Previous history.—Pneumonia when aged 1 year.

Family history.—No family history of goitre. Both parents healthy. One other child, aged 5 months, appears normal.

On examination.—Normal intelligence. Marked bilateral exophthalmos. All eye signs for exophthalmos. Diffuse enlargement of thyroid gland, smooth surface. Right lobe larger than left. Tremor of fingers on stretching out arms. Sleeping pulse average 120. Heart: within normal limits, heart sounds normal.

Investigations.—X-ray skull: No gross abnormality, pituitary fossa normal. X-ray chest normal, no retrosternal goitre. Blood cholesterol 135 mg. per 100 c.c. W.R. and Khan negative. Blood-count: Hb. 88%; W.B.C. 6,000; normal differential. E.C.G. shows tachycardia. B.M.R. not possible owing to patient's age. Rough test by Reed's formula + 54. Weight: 7.10.46, 1 st. 9 lb. 12 oz. 8.11.46, 1 st. 7 lb. 3 oz.

Treatment.—Methyl thiouracil 0·1 gramme q.i.d. for three days, started on 7.11.46. Thereafter 0·1 gramme t.d.s.

POSTSCRIPT (18.2.47).—The child was discharged from hospital and developed an upper respiratory infection which caused her readmission. At the same time she had two severe attacks of tachycardia, her pulse rising to 130-140. She has since been discharged quite fit and her pulse steady. She has been continuing with thiouracil. It is hoped to report on this case again later.—G. S.

Calcinosis Universalis.—A. P. NORMAN, M.B. (for DONALD PATERSON, F.R.C.P.).

G. H., female, aged 3½ years.

Normal birth; milestones passed normally. Brother and sister alive and well.

At the age of 17 months the child stopped crawling and objected to her limbs being moved; since then she has made no attempt to move about, but will support herself if sat up. At the age of 2 years she developed abscesses on the buttocks; a few months later hard lumps were noticed in the skin around the lower ribs.

Examination on 29.5.46 showed a small child, not thin, the face pink with a violet tinge, especially round the eyes, the skin smooth and glossy. No visceral or neurological abnormality found. Scars of healed abscesses on buttocks. Wasting of buttocks and legs. Limitation of movement at hip, knee and ankle, any attempt at movement causing great distress. Hard nodules about the size of a pea were present deep to the skin of upper thighs and lower ribs, mostly posteriorly. Recent examinations show slight improvement in joint movement.

Radiological findings (3.6.46).—Widespread deposit of calcium in soft tissues; calcium content of bones possibly diminished.

Biochemistry.—Serum calcium 9·5 mg. per 100 c.c. Alkaline plasma phosphatase 8·4 units. Inorganic blood phosphorus 4·1 mg. per 100 c.c. Blood cholesterol 136 mg. per 100 c.c. B.S.R. 39 mm. in one hour.

Blood-count.—R.B.C. 4,500,000; Hb. 95% (13·3 grammes); W.B.C. 10,000 (polys. 34%, lymphos. 64%, eosinos. 2%).

Biopsy report (Dr. Martin Bodian).—Epidermis is thin and keratinization not well marked. The corium contains a thick layer of dense collagen which does not interfere with nutritional supply of hair follicles, arrectores pilorum and sweat glands. Beneath the collagen is a layer of normal fat and beneath this are large nodules of necrotic fat cells; there is also calcification. The nodules are surrounded by fibrous tissue bands with small clusters of lymphocytes. There is hyaline degeneration of muscle with loss of cross striation and small clusters of lymphocytes are present in the intermuscular septa.

Dr. Herbert Levy drew attention to a paper by J. J. C. P. A. Rovers (*Acta. med. Scand.*, 1939, 100 57) which reported complete recovery from severe calcinosis universalis in a girl aged 5 following two courses of five weeks' treatment with sodium citrate (3 grammes daily) and occasional intravenous administration of calcium gluconate. This treatment had been suggested by Professor Snapper because of the increased ability of the plasma proteins to bind calcium when the reaction of the blood is changed in an alkaline direction. Serum calcium and inorganic phosphate rose during the treatment up to double the normal levels.

Dr. Levy had himself observed disappearance of peri-articular calcification in an adult after such treatment but spontaneous recovery occasionally occurs.

Sclerema.—A. P. NORMAN, M.B. (for DONALD PATERSON, F.R.C.P.).

G. P., male, aged 11 months. (Born 11.12.45.)

Full-term child, with normal delivery, but history of septicæmia in the mother during pregnancy. At five months the right wrist became red and swollen, and two days later the left wrist became similarly affected and later the legs became swollen and hard but not red. He had slight fever for one week and was treated with penicillin without effect.

On admission the child was apyrexial and notably happy; the skin of the face seemed pale, glazed and greyish; firm plaques were palpable under and attached to the skin on thighs, legs, feet and arms.

Radiological report (25.6.46).—Thickening of the soft tissues and coarsening, with shadows almost of the density of calcium.

Blood-count.—R.B.C. 4,600,000; Hb. 95% (13·3 grammes); W.B.C. 17,500 per c.mm. (polys. 54%, stabs 4%, lymphos. 31%, monos. 6%, eosinos. 5%).

B.S.R. 9 mm. in one hour.

Post-nasal swab.—A few colonies of coagulase-positive *Staph. aureus.*

Biopsy report (Dr. Martin Bodian).—In the corium there are clusters of large fat cells with few nuclei, surrounded by fibrous tissue and giant cells. There is evidence of calcification confirmed by von Kossa stain. A few vessels show endarteritis obliterans of various degrees. Doubly refractile crystals present within the fat cells, giving the staining reactions of neutral fat.

Congenital Syphilis.—J. HEBER, M.B., B.S. (for MARY WILMERS, M.D.).

Peter J., aged 2 months. Weight 9 lb. 15 oz.

History.—Severe snuffles and a thick purulent nasal discharge since birth. Peeling of hands and feet noticed for three weeks. Macular rash noticed two weeks ago.

Family history.—Father away in the Army in Greece. Returned home on leave for one month in December 1945 and in May 1946. No discharge, sores or rash noticed by the wife at this time. She is alive and well and never has had any symptoms. Normal pregnancy, leading to the normal delivery of a 7 lb. baby. No treatment during pregnancy. Three other children all alive and well. One miscarriage in 1943 at three months.

On examination.—A typical congenital syphilitic with severe snuffles, enlarged liver and spleen, typical rash on lower limbs and buttocks; anal fissures, maculopapular rash down the inner sides of the legs with reddened, peeling palms of hands and soles of feet. Early rhagades. No clinical epiphysitis.

Investigations.—W.R. and Kahn positive in both mother and baby. Baby's blood-count: R.B.C. 3,800,000; Hb. 68%; W.B.C. 9,000. Differential normal. X-ray of long bones: Marked periostitis. Some epiphysitis.

Treatment.—Mercury inunctions, given as an out-patient for two weeks with no improvement. Then penicillin, total dose 120,000 units per kg. body-weight, in 60 doses at four-hourly intervals, combined with daily mercury inunctions.

Progress.—After three days general condition much improved and gained weight. Rash disappeared; snuffles decreased with marked diminution of the nasal discharge, rhagades treated.

Tuberculous Abscess Formation following Penicillin Therapy.—P. J. COOPE, M.B. (for J. C. R. HINDENACH, F.R.C.S.).

C. B., male, aged 2 years 9 months.

14.9.46: Admitted with indurated swelling in left side of neck of one week's duration. Swelling incised, the pus found being sterile on culture and a few Gram-positive cocci seen on direct smear. Penicillin in saline afterwards given by injection into muscles of buttocks and thighs. Total 800,000 units. Wound healed and child discharged on eleventh day.

29.9.46: Readmitted with abscesses in the left thigh and groin and right buttock, those in thigh and buttock appearing to be deeply situated. Pus from all three abscesses contained tubercle bacilli and was sterile on culture. General condition of child good. Temperature range 97° to 100°. Abscesses are showing a tendency to reform and have been aspirated again.

Other investigations.—X-rays: No lesion in chest or spine. Tuberculin jelly test: strongly positive on 4.11.46. Blood-count: Slight hypochromic anæmia. White count and differential normal. E.S.R.: 11 mm. in one hour on 8.11.46; 18 mm. in one hour on 21.11.46.

One previous case has been reported by Ebrill and Eleck. A boy developed a tuberculous abscess in the thigh four months after a continuous intramuscular injection of penicillin in that site. The original infection for which the penicillin was given was a staphylococcal axillary abscess. It was considered by these workers that, as they could find no primary lesions in the boy, the infection was caused by the introduction of tubercle bacilli at the time of the penicillin injection. Hounslow considered that this abscess occurred as the result of a hæmatogenous spread from some primary focus elsewhere, and a hæmatoma at the site of infection forming a nidus of lowered resistance for the tubercle bacilli.

In the case presented here the fact that abscesses were present in both thighs suggests a hæmatogenous mode of infection. It is assumed that the one in the left groin was due to lymphadenitis draining that in the left thigh. It is a possibility, though unproven, that the original cervical abscess was tuberculous, as the pus was sterile. The alternative hypothesis regarding the mode of infection, also unproven, would, of course, be via contaminated syringes or needles. A special 1 c.c. syringe is kept for penicillin injections and is not used for aspirations.

Juvenile Cirrhosis.—URSULA JAMES, M.B., M.R.C.P.

Shirley G., aged 7 years 8 months.

Attended Victoria Hospital for Children as out-patient on 1.10.45, then aged 6½ years. Sent by private doctor for advice about tonsils. Backward in walking and talking (2 years+); had been taking thyroid extract ½ grain daily for four years when first seen. In 1945 normal standard at school, but spiteful, sharp-tempered and destructive. Weight 4 st. 3 lb. Tonsils large, infected. Stance round shouldered. Liver and spleen palpable and enlarged.

Family history.—One younger sibling normal. Some relatives on father's side stated to be dark skinned. Otherwise nothing relevant.

Past personal history.—Her mother had normal pregnancy and delivery. No neonatal jaundice. Pertussis, measles, mumps, bronchitis. No blood transfusions.

First admission 24.11.45.

On examination.—Dark skinned, adenoid facies, high arched palate, mouth breather. Liver firm, palpable two fingerbreadths below costal margin. Spleen firm, enlarged to umbilicus. Feet—polydactyly.

Investigations.—R.B.C. 4·2 millions. No primitive cells. Hb. 96%. W.B.C. 3,000 (polys. 69%, lymphos. 23%). Urine normal. Wassermann reaction negative. Sternal puncture: normoblastic marrow. No Gaucher's cells. Increased numbers megakaryocytes.

Discharged undiagnosed 23.12.45. Thyroid ½ grain daily continued.

Readmitted 18.2.46: Tonsillectomy and adenoidectomy. Uneventful convalescence. Discharged 8.3.46. Attended as out-patient monthly until the next admission.

April 1946: Weight 4 st. 10 lb. Spontaneous bruising of limbs noticed.

June: Liver and spleen i.s.q. Van den Bergh negative direct. Serum bilirubin 1·4 mg.% Serum proteins 8 grammes%. R.B.C. 3·7 millions; Hb. 72%; W.B.C. 4,800 (polys. 49%, lymphos. 37%, monos. 11%).

July: Red cell fragility—hæmolysis commenced 4·5% NaCl, complete at 3% NaCl. Systolic apical murmur. Hot and sweating. Emotional, with "tantrums". Thyroid stopped 22.7.46. Iron by mouth started.

August: Weight 5 st. 1¾ lb. (rapid gain since stopping thyroid). Diet—carbohydrate restriction—commenced.

September: Weight 4 st. 12 lb. Exophthalmos, fine tremor of hands, von Graefe's sign noted. Pulse 92. Otherwise physical signs unchanged. R.B.C. 4·1 millions;

Hb. 80%; W.B.C. 6,400 (polys. 70%, lymphos. 25%, monos. 5%). Blood cholesterol 276 mg.%. Mother and child Rh positive. No Rh antibody in the maternal serum. B.S.R. 10 mm. in one hour (micro-method). X-ray skull and long bones normal.

October: Weight 4 st. 12 lb. Previous physical signs unaltered except thyroid gland noted to be easily palpable. Blood sugar curve: Fasting 93 mg.%. 115 mg.% after 2½ hours. Maximum rise 133 mg.%. No glycosuria. Platelet count normal.

Readmitted 28.10.46: R.B.C. 4·3 millions; Hb. 82%; W.B.C. 6,000 (polys. 51%, lymphos. 43%, monos. 6%). Sternal puncture—Gaucher's cells absent. Normal marrow picture. Biopsy of skin—intense melanin deposit in basal layers, no hæmosiderin. Blood: Cholesterol 258 mg.%. Thymol turbidity 3 units. Alkaline phosphatase 49 units. Serum bilirubin 1·2 mg.%. Van den Bergh delayed, weakly positive.

November 26: Laparotomy. Spleen smooth, very vascular, enlarged to umbilicus. Liver small, rounded margin, hard. Liver section for biopsy. Uneventful convalescence. Discharged home 8.12.46.

Biopsy of liver (Dr. J. D. Gray).—The architecture of the liver has altered: the lobular pattern replaced by strands of fibrous tissue spreading out from the portal spaces cutting the lobules into an irregular pattern. The bile ducts are dilated and here and there small ducts unrelated to the portal spaces can be seen lying in the fibrous tissue strands. In other peri-portal areas are collections of lymphocytes, polymorphs and fibroblasts. In the liver parenchyma the bile canaliculi are dilated; thrombi were not seen. The liver cells are not remarkable.

Discussion on pathological findings.—From the biochemical point of view the persistently high blood cholesterol, high blood alkaline phosphatase and moderately increased plasma bilirubin were suggestive of a liver lesion of the obstructive type. More evidence was obtained when the abnormal blood sugar curve was fitted into the pattern—for it indicated the probability of liver parenchymal destruction. When these facts were related to the clinical observations a cirrhotic liver appeared to be the most likely consideration. The presence of a normal thymol turbidity test was not unexpected as the plasma protein estimation had shown no pathological variation. The histological picture was therefore in complete keeping with the biochemical findings.

The recent work of Dible *et al.* on the relationship between infective hepatitis and cirrhosis should be borne in mind when considering multilobular cirrhosis—as exhibited by the histological picture this case presents. A preceding zonal and focal necrosis with the necrotic parenchymal tissue replaced by the proliferating ducts and their attendant fibroblasts could be visualized when studying the sections.

A diagnosis of multilobular cirrhosis of the liver with congestive spleen has been made in this case, but the label does not embrace the mental retardation, the thyroid changes with a transient hyperthyroidism and the excessive weight. The ætiology of the cirrhosis is not known; there is no previous history of any illness that might predispose to its development.

Hepatosplenomegaly: For Diagnosis.—C. F. SAUNDERS, L.R.C.P., M.R.C.S. (for PHILIP EVANS, F.R.C.P.).

Male, aged 4 years 10 months. Only child. Birth weight 6 lb. 13 oz. Did not gain well in infancy. At age 7 months to 10 months he was in hospital with measles and whooping cough. Weight 10 lb. at age of 10 months. Frequent colds since then and has remained thin, but otherwise well.

On examination.—6.11.46: Liver enlarged two fingerbreadths, sharp edge. Spleen enlarged ½ inch below umbilicus, smooth, not tender.

27.11.46: Generalized glandular enlargement. Glands discrete, not tender. Temperature 101°. The spleen now reaches to the left pubic ramus.

Investigations.—Blood-count: R.B.C. 4,880,000; Hb. 84%; C.I. 0·87; W.B.C.

6,400 (polys. 56%, lymphos. 43%, monos. 1%). Fragility of R.B.C.: No hæmolysis in 0·46% NaCl. Serum cholesterol 174 mg. per 100 ml. W.R. negative. Tuberculin jelly test negative. Urine normal. Lævulose tolerance test normal. Blood urea 32 mg. per 100 ml. Van den Bergh reaction: direct, negative; indirect, total bilirubin less than 0·2 mg. per 100 ml. Thymol turbidity test 5 units. Total serum proteins 6·25 gm. per 100 ml. Albumin globulin ratio in serum: 2·51 : 1. Repeat blood-count (30.11.46): R.B.C. 3,000,000; Hb. 56%; W.B.C. 7,000 (polys. 36%, lymphos. 64%).

Intracranial Hæmangioma Causing Convulsions.—M. W. WEST, M.B. (introduced by R. C. LIGHTWOOD, M.D.).

Kenneth M., aged 9 years.

17.10.46: Admitted to hospital. Had suffered from convulsions for the past eighteen months, increasing in frequency.

History.—Full-term child, birth weight 5½ lb. Difficult breech delivery, forceps employed. Was not expected to live; cyanosed for three weeks and did not cry normally for a month. However, development was normal, child was in fact somewhat "forward". Sat up at 7 months, walked at 12 months and talked at 18 months. Left internal strabismus noticed at age 2 weeks. Two operations for this. Measles at 3 years.

History of present condition.—First convulsion eighteen months ago. Since then convulsions have occurred monthly until six months ago, since when three-weekly, fortnightly and finally three or four times a week. None for three weeks until child had one shortly before admission (13.10.46). Convulsions are nocturnal and are preceded by a cry. Right arm and leg twitch, there is frothing at the mouth and the head jerks towards the right. This clonic stage lasts fifteen to twenty minutes and is followed by flaccidity lasting five to ten minutes before motor power returns. No incontinence during convulsions but patient occasionally vomits. Has never had sedatives.

On examination.—Intelligent normal child. No abnormal physical signs beyond tendency to left internal deviation.

Investigations.—X-ray skull: Oval area of very thin bone to right of internal occipital protuberance. Prominent vascular channel taking origin in two groups of diploic veins and running across R. parietal bone. Slight asymmetry of vault. Volume of L. hemicranium greater than R. Air encephalogram gave no additional information. Radiologist's opinion that appearances were suggestive of intracranial hæmangioma and that there was likelihood of additional information being obtained by arteriography did not justify the risks of such procedure. E.E.G.: Repeated bursts of atypical "spike and dome" waves L. hemisphere, seen diffusely but mostly in cerebral area. No single focal area: Suggests diffuse, probably atrophic lesion, L. hemisphere. It was proposed to treat this case by X-radiation.

Angioma of the Basal Ganglia.—L. J. ROWLEY, M.B. (for DONALD PATERSON, F.R.C.P., and WYLIE MCKISSOCK, O.B.E., M.S.).

P. C., boy aged 9 years.

Attended Out-Patients' Department with a history of the onset of a limp four years ago. Six weeks ago was noticed to be using his left hand more than his right. He also had weakness of the right side of his face which his mother said had been present all his life.

Abnormal physical signs.—Bruit best heard over the left eyeball and left side of the head. Nævus, a very faint "port wine stain" above the left eye. Fundi: Right is normal, left shows tortuosity and dilatation of the veins, but no hæmangiomatous formation. Hemiparesis on the right side: (1) Upper motor type of facial paresis; (2) weakness, wasting and hypotonicity, more marked in the arm than in the leg;

(3) plantar responses, Rt. extensor, Lt. flexor. Eye movements: (1) Limitation of elevation; (2) inability to converge.

Investigations.—X-rays of skull show no abnormality. Ventriculogram shows displacement of the lower and anterior part of the third ventricle to the right. This indicates an expanding lesion in the left caudate nucleus. Angiography: Antero-posterior and lateral views show a large angioma of the left basal ganglia.

Treatment.—Deep X-ray therapy. Dose 2,250 r units.

Result.—No improvement one week after completing the course of treatment.

Staphylococcal Pneumonia with Obstructive Emphysema.—L. G. SCOTT, M.B., B.S. (for DONALD PATERSON, F.R.C.P.).

D. S., male. Admitted 28.8.46, aged 3 weeks.

History.—A small spot appeared on his chin one week previously which became septic. Two or three more septic spots appeared on the chin and a submandibular abscess was opened one day before admission. A slight cough and grunting respirations were present for three days before admission.

On examination.—Temperature 102°; pulse 122; respirations 59. Not cyanosed. Impaired percussion note over the right side anteriorly and in the right upper zone posteriorly. Râles all over the right side of the chest. The submandibular abscess was discharging and the umbilicus was sticky.

Investigations.—Blood culture and swabs from throat, umbilicus and boil grew coagulase-positive *Staph. aureus.* X-ray of chest: collapse and consolidation in the right upper lobe. W.B.C. 35,500 per c.mm. (polys. 71%, lymphos. 29%).

Progress.—Baby became very ill and cyanosed, and X-ray on 3.9.46 showed clearing in the right upper lobe and an opacity in the right lower lobe. The general condition then improved and on 9.9.46 X-ray showed a cystic appearance at the right base. The mediastinum subsequently became greatly displaced towards the left side by the obstructive emphysematous condition on the right side. The chest was needled on 19.9.46 in the fifth space in the mid-axillary line on the right side and about 15 to 20 c.c. of air removed which did not appear to be under great pressure. There was slight relief of the mediastinal displacement. About this time the baby's condition again deteriorated and he had very loose stools. He eventually improved and on 9.10.46 X-ray showed the mediastinum to be approximately central although there was still a cystic appearance on the right side. Discharged on 14.10.46, gaining weight slowly (weight 7½ lb.).

He was last seen as an out-patient on 11.11.46 and he had then gained 2 lb. 3 oz. in weight since discharge. X-ray of his chest showed some collapse in the right upper lobe. The case is being kept under observation.

Treatment.—Penicillin 3,000 units four-hourly intramuscularly (total of 585,000 units). A course of sulphathiazole (3·75 grammes) and later of sulphadiazine (total 6 grammes) was given. The baby was nursed in an oxygen tent for about one month and a penicillin spray was given in this for forty-eight hours on 11 to 13.9.46. A blood transfusion of 120 c.c. was given on 14.9.46 (R.B.C. 3,900,000 per c.mm. two days previously).

Spontaneous Bilateral Pneumothorax Occurring in a Premature Baby During the Neo-Natal Period.—JEAN W. PAUL, M.B. (for S. YUDKIN, M.R.C.P.).

R. S., male, aged 16 days, was admitted on October 4, 1946, with a history of a convulsive attack occurring half an hour after the 6 p.m. feed on that day. No previous similar attacks had been noticed by the mother.

The birth had occurred thirty-eight days prematurely following a second mild antepartum hæmorrhage. The delivery had been normal and the birth weight was 4 lb. 10 oz. Jaundice and cyanosis had been noticed during the first few days and the child had some difficulty in sucking. After discharge from the Maternity

6,400 (polys. 56%, lymphos. 43%, monos. 1%). Fragility of R.B.C.: No hæmolysis in 0·46% NaCl. Serum cholesterol 174 mg. per 100 ml. W.R. negative. Tuberculin jelly test negative. Urine normal. Lævulose tolerance test normal. Blood urea 32 mg. per 100 ml. Van den Bergh reaction: direct, negative; indirect, total bilirubin less than 0·2 mg. per 100 ml. Thymol turbidity test 5 units. Total serum proteins 6·25 gm. per 100 ml. Albumin globulin ratio in serum: 2·51:1. Repeat blood-count (30.11.46): R.B.C. 3,000,000; Hb. 56%; W.B.C. 7,000 (polys. 36%, lymphos. 64%).

Intracranial Hæmangioma Causing Convulsions.—M. W. West, M.B. (introduced by R. C. Lightwood, M.D.).

Kenneth M., aged 9 years.

17.10.46: Admitted to hospital. Had suffered from convulsions for the past eighteen months, increasing in frequency.

History.—Full-term child, birth weight 5½ lb. Difficult breech delivery, forceps employed. Was not expected to live; cyanosed for three weeks and did not cry normally for a month. However, development was normal, child was in fact somewhat "forward". Sat up at 7 months, walked at 12 months and talked at 18 months. Left internal strabismus noticed at age 2 weeks. Two operations for this. Measles at 3 years.

Section of Anæsthetics

President—Stanley Rowbotham, M.D.

[*December* 6, 1946]

DISCUSSION: SHOCK WITH SPECIAL REFERENCE TO ANÆSTHESIA

Professor H. N. Green: It is with some hesitation that I discuss the relationship between anæsthesia and shock because, whilst we know the exciting factors and some of the manifold reactions in these two general states, we know little of the fundamental mechanisms involved in either. To interrelate two unknown mechanisms is impossible and any attempt must therefore be purely speculative. Unfortunately speculation and dogma are the highlights of innumerable discussions on shock. However, comparable experimental data concerning the part that anæsthetics play in the induction of or prevention of shock are so few that we must perforce in some degree guess how the two conditions may react on each other. It must from the start be emphasized that we are guessing and by doing so emphasizing the need for more refined experimental observation.

Among the most important questions requiring answers are the following:

(1) Are general anæsthesia and shock completely different or completely similar states, or have they merely certain common features? Are therefore their effects independent or reinforcing, or are they even antagonistic?

Less theoretical questions, though intimately linked with the first are:

(2) Does the dose of anæsthetic required vary inversely with the degree of shock and if so what is the quantitative relationship?

(3) What anæsthetic, or combination of anæsthetics, least favours the induction of shock by tissue injury and is this same anæsthesia necessarily best in established shock?

(4) Does, in fact, shock still remain an important problem for the anæsthetist or has modern anæsthesia so developed that it has automatically established the conditions least damaging to the tissues and therefore to the promotion of shock?

To none of these questions is there a complete answer but all are germane to the topic and I will speculate briefly on some of the points raised, in the hope that discussion may be provoked.

Between general anæsthesia and shock there are superficial resemblances, for the severely shocked patient is well on the way to unconsciousness and in both conditions there is a general depression of all vital activities. The blood-pressure falls, the respirations become slow and shallow, there is profound muscular relaxation and the body temperature is low. In anæsthesia the higher nervous centres are more profoundly affected than in shock but in the advanced stages of shock loss of consciousness, as evidenced by absence of response to painful stimuli and diminu-

Hospital he had been breast-fed satisfactorily without any apparent cyanosis or difficulty in sucking.

It was the ninth pregnancy. There had been no previous premature births or miscarriages, all previous deliveries had been normal, and no congenital defects had been noted in any of the family. Both parents are in good health.

On admission to the Casualty Department, soon after the convulsion, the baby was very collapsed and pale, but no cyanosis or respiratory difficulty was noted. The baby made a quick recovery, and subsequently nothing abnormal was noted on physical examination, and there were no abnormal physical signs in the lungs.

A provisional diagnosis of a cerebral attack associated with prematurity was made, but a routine X-ray of chest on the following day showed a bilateral pneumothorax. Four days later X-ray showed re-expansion of the left lung.

The baby was discharged from hospital on October 9. X-ray on the 17th showed no change, but by November 2 complete re-expansion had taken place.

Thus complete resolution of the condition occurred within twenty-eight days of the diagnosis having been made, and at no time had there been any physical signs or symptoms of a pneumothorax.

The majority of reported cases of pneumothorax in the newborn have been associated with difficult births, asphyxia, or attempts at artificial respiration. These cases have usually shown definite evidence of the condition and have been called spontaneous *pneumothorax abrupta*. A second group of cases in which symptoms have developed gradually have been termed spontaneous *pneumothorax lenta* and infective processes and congenital lung defects have been included in the ætiology.

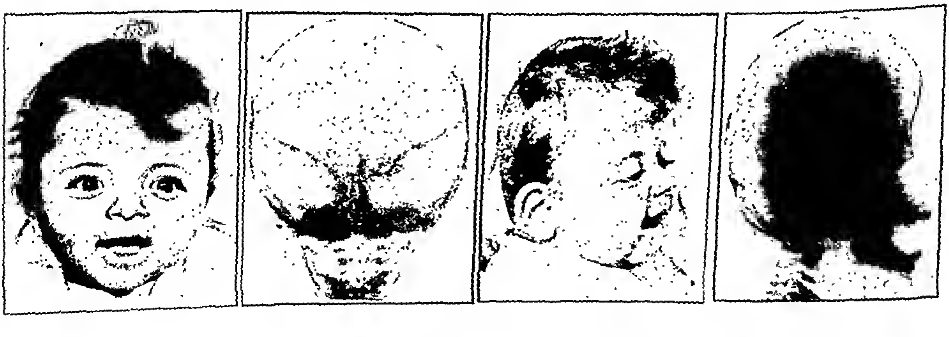
In 1940 De Costa (*Amer. J. Obstet. Gynec.*, **39**, 378) put forward the view that the condition may occur more commonly than is generally recognized; and in 1930 a routine radiographic review of 702 newborn babies (Davies and Stevens, *Amer. J. Obstet. Gynec.*, **20**, 73) included six cases of symptomless pneumothorax.

This case seems to fall into this third class of symptomless pneumothorax, which would have remained undiagnosed in the absence of a routine X-ray.

It was suggested that the pneumothorax might have occurred during the convulsive attack; but in view of the occasional cyanosis noted in the first few days after birth, it was felt that the possibility of a long-standing pneumothorax dating from birth could not be excluded.

Oxycephaly.—PHILIP EVANS, M.D.

Boy aged 7 months. Mother and father healthy, not consanguineous. Pregnancy and labour normal. Head of baby noticed to be abnormal in shape at birth.



Oxycephaly. Infant aged 7 months.

On examination.—Child healthy, weight 18½ lb., head circumference 16¼ in. Typical appearance of oxycephaly without exophthalmos. Anterior fontanelle admits finger tip; metopic suture not felt, other suture lines palpable.

The child is bright, cheerful and without obvious visual disturbance.

hæmorrhagic shock (Bennett *et al.*, 1944) and the work of the M.R.C. Committee (1918) on acidosis and shock showed how easily ether in excessive amounts would precipitate shock in artificially induced acidosis in the cat. The possibility of overdosage is, however, always to the fore. For instance, Lorbor *et al.* (1940) claimed in opposition to O'Shaughnessy and Slome (1935), that deep anæsthesia in cats favoured the onset of traumatic shock, for under ether *analgesia* the animal was more resistant to shock than under chloralose or nembutal anæsthesia. The interpretation of all experimental work on shock is complicated by the extra factor of anæsthesia and unfortunately, as in clinical work, the choice of anæsthetic often depends on the anæsthetist being experienced in one type of anæsthesia. For this reason there is not much guide in the literature to the relative merits of different anæsthetics in either potential or established shock. The observations of Bennett *et al.* (1944) are the best recent approach to this problem. They compared the effects of sodium evipan, ether and cyclopropane on the circulation of dogs before and after the induction of hæmorrhagic shock. They conclude that cyclopropane offers the best margin of safety with respect to blood-pressure and blood flow through essential vascular beds. It is impossible to compare the normal and anæsthetized animal but it should be possible to compare a wide range of anæsthetics at the same degree of anæsthesia. Now that more standardized methods of shock induction, particularly that of limb ischæmia in rodents, have been evolved such an arduous investigation could now be undertaken. Only thus might the precise information, which we now completely lack, be obtained.

My own experience provides but little practical help in the problem but does not suggest that all anæsthetics necessarily lower the tolerance to shock-inducing methods. For instance neither light ether nor anæsthetic doses of the barbiturate nembutal, significantly increase the susceptibility of rats to adenosine triphosphate shock and there are indications that ether analgesia may decrease it. Here I must digress to explain this method of shock induction and a curious relationship of an unusual anæsthetic to it.

I have shown (Green, 1943) that pure adenosine triphosphate obtained from muscle (Bielschowsky and Green, 1943) is capable of producing a shock-like state when injected into a wide variety of animals. This substance has a wide distribution in the body and is of great physiological importance, for by the high energy potential of its terminal phosphate bond it provides the energy for muscular contraction and no doubt for many other energy transformations in the body. Now in the presence of a raised tissue magnesium content the effective dose of adenosine triphosphate is strikingly reduced (Green and Stoner, 1944). Moreover, under similar conditions the shock-inducing action of tissue injury is enhanced or accelerated. Here then is a substance, magnesium, with anæsthetic properties which increases the susceptibility of the organism to shock-inducing stimuli. Or the result may be interpreted as that of a shock-inducing agent increasing the susceptibility to an anæsthetic. A correct interpretation is not so simple as it might appear because magnesium anæsthesia and fully developed adenosine triphosphate shock are, superficially at least, strikingly similar. These findings have obviously some importance in relation to the mechanism of shock and possibly to the rôle which adenosine triphosphate undoubtedly plays in it. They have, however, no immediate relevance to the relation between anæsthesia and shock for no such potentiation of adenosine triphosphate is brought about by ether or nembutal. It may be noted, however, that as this form of shock develops, the effective dose of anæsthetics, as with shock however induced, is progressively reduced, until a point is reached at which shock from a practical standpoint is itself anæsthesia.

It was the observation of the anæsthetic state seen in advanced adenosine triphosphate shock which led me to consider a possible relationship between the two tion or absence of the corneal reflex may be observed in an animal which still retains the power of recovery. Such observations are made more readily in the experimental animal and indeed there may be no obvious difference between the appearance of an animal in deep shock and in deep anæsthesia.

Apparent similarities are to be found when we probe somewhat deeper. The oxygen consumption of the body (McClure *et al.*, 1939) and of individual tissues (Quastel, 1932) falls in response to anæsthetics and this fact is one of the most prominent features of the shock state as Aub (1920) first clearly demonstrated in cats following trauma to the hind limbs. Though the reported blood volume changes in general anæsthesia are variable with some anæsthetics, particularly ether, hæmoconcentration and a fall in volume have been recorded (Boycott and Price-Jones, 1922; Stewart and Rourke, 1938). Are these similarities merely fortuitous or do they indicate some more fundamental connexion between the two states? We do not know but there are some practical and theoretical considerations which suggest that the possibility of some common factor in the mechanism of shock and anæsthesia might be further explored.

In established shock I imagine that no anæsthetist would dispute the statement, and it is certainly my experience in experimental shock, that the amount of anæsthetic required to produce full anæsthesia is very much reduced and varies inversely with the degree of shock. More exact quantitative data are, however, required, particularly as I am sure the figures would be impressive enough to make no one, even the most inexperienced, question the ever-present danger of overdosage in established shock. On the question of whether anæsthetics render the animal more sensitive to shock-inducing agents, we are not on such firm ground. Clinical observations in the 1914-18 war by Marshall (1917) and Cannon (1923) suggested that ether and chloroform anæsthesia, as judged by their effect on blood-pressure and post-operative complications could be highly dangerous in the severely injured though not necessarily clinically shocked man. Later laboratory investigations indicated that their effect on blood-pressure was mainly due to a depressant action on heart muscle. Nitrous oxide, with efficient oxygenation, had not this effect and these observers found this by far the most satisfactory anæsthetic for battle casualties. Their observations were given apparently strong support by the observation of Dale (1919) that the etherized cat was far more susceptible to the shock-inducing action of histamine than was the unanæsthetized or nitrous oxide and oxygen anæsthetized animal. The obvious difficulty in interpreting such results is that two different levels of anæsthesia were being compared and moreover the ether anæsthesia could well have been so deep as to complicate the experiment by adding the effects of tissue anoxia and overdosage. Since it is now known that histamine is not responsible for traumatic shock the observations are not so pertinent to the clinical problem as at one time appeared.

There is, of course, no doubt that, anæsthetics, being potentially toxic agents, can, at some concentration within the recoverable range produce tissue damage, or that an associated tissue anoxia will produce additional damage. But, and here I am open to correction, there is no absolute proof that every type of anæsthesia must necessarily produce these secondary effects in any significant degree. There are, of course, plenty of experimental and clinical observations suggesting that some general anæsthetics do make the organism more susceptible to shock. Chloroform in particular has long been suspect both in the clinics and laboratory, and in experimental work chloralose has a bad reputation (Freedman and Kabat, 1940). In fact, Blalock and Cressman (1939) suggested that good results with spinal anæsthesia in traumatic shock (O'Shaughnessy and Slome, 1935) might have been due to a protective action against the convulsive effect of chloralose. Even ether has been reported to increase the susceptibility of cats to traumatic shock (Kabat, 1940) and dogs to hæmorrhagic shock (Bennett *et al.*, 1944) and the work of the M.R.C. Committee (1918) on acidosis and shock showed how easily ether in excessive amounts would precipitate shock in artificially induced acidosis in the cat. The possibility of overdosage is, however, always to the fore. For instance, Lorbor *et al.* (1940) claimed in opposition to O'Shaughnessy and Slome (1935), that deep anæsthesia in cats favoured the onset of traumatic shock, for under ether *analgesia* the animal was more resistant to shock than under chloralose or nembutal anæsthesia. The interpretation of all experimental work on shock is complicated by the extra factor of anæsthesia and unfortunately, as in clinical work, the choice of anæsthetic often depends on the anæsthetist being experienced in one type of anæsthesia. For this reason there is not much guide in the literature to the relative merits of different anæsthetics in either potential or established shock. The observations of Bennett *et al.* (1944) are the best recent approach to this problem. They compared the effects of sodium evipan, ether and cyclopropane on the circulation of dogs before and after the induction of hæmorrhagic shock. They conclude that cyclopropane offers the best margin of safety with respect to blood-pressure and blood flow through essential vascular beds. It is impossible to compare the normal and anæsthetized animal but it should be possible to compare a wide range of anæsthetics at the same degree of anæsthesia. Now that more standardized methods of shock induction, particularly that of limb ischæmia in rodents, have been evolved such an arduous investigation could now be undertaken. Only thus might the precise information, which we now completely lack, be obtained.

My own experience provides but little practical help in the problem but does not suggest that all anæsthetics necessarily lower the tolerance to shock-inducing methods. For instance neither light ether nor anæsthetic doses of the barbiturate nembutal, significantly increase the susceptibility of rats to adenosine triphosphate shock and there are indications that ether analgesia may decrease it. Here I must digress to explain this method of shock induction and a curious relationship of an unusual anæsthetic to it.

I have shown (Green, 1943) that pure adenosine triphosphate obtained from muscle (Bielschowsky and Green, 1943) is capable of producing a shock-like state when injected into a wide variety of animals. This substance has a wide distribution in the body and is of great physiological importance, for by the high energy potential of its terminal phosphate bond it provides the energy for muscular contraction and no doubt for many other energy transformations in the body. Their observations were given apparently strong support by the observation of Dale (1919) that the etherized cat was far more susceptible to the shock-inducing action of histamine than was the unanæsthetized or nitrous oxide and oxygen anæsthetized animal. The obvious difficulty in interpreting such results is that two different levels of anæsthesia were being compared and moreover the ether anæsthesia could well have been so deep as to complicate the experiment by adding the effects of tissue anoxia and overdosage. Since it is now known that histamine is not responsible for traumatic shock the observations are not so pertinent to the clinical problem as at one time appeared.

There is, of course, no doubt that, anæsthetics, being potentially toxic agents, can, at some concentration within the recoverable range produce tissue damage, or that an associated tissue anoxia will produce additional damage. But, and here I am open to correction, there is no absolute proof that every type of anæsthesia must necessarily produce these secondary effects in any significant degree. There are, of course, plenty of experimental and clinical observations suggesting that some general anæsthetics do make the organism more susceptible to shock. Chloroform in particular has long been suspect both in the clinics and laboratory, and in experimental work chloralose has a bad reputation (Freedman and Kabat, 1940). In fact, Blalock and Cressman (1939) suggested that good results with spinal anæsthesia in traumatic shock (O'Shaughnessy and Slome, 1935) might have been due to a protective action against the convulsive effect of chloralose. Even ether has been reported to increase the susceptibility of cats to traumatic shock (Kabat, 1940) and dogs to favourable aspects of anæsthesia and shock induction. Do anæsthetics, for instance, reduce cell membrane permeability and thus restrict local fluid and electrolyte losses at the site of injury? For instance one prominent theory of anæsthetic action relates it to the redistribution in the cell membrane of surface lipoids with diminished permeability to water and water-soluble substances. On the experimental side there is the work of Pickrell (1940) who finds that anæsthetics of various kinds prevent the vascular response in infected tissues and thus presumably diminish local exudation. Slender though this evidence may be it does serve to remind us that anæsthetics may well have a therapeutic, and not merely a harmful rôle in shock.

There is another more general aspect of the problem which ought to be considered in the present context. Since I first started the study of shock in 1941 I have always expressed the view to my assistants that there is no evidence that shock is necessarily, in itself, a pathological, in the sense of harmful, state. Just as inflammation is the local reaction to injury, shock is the early general reaction, and, like inflammation, must surely be a physiological defence mechanism. There is not time here to expound this view in full. Suffice to say that every manifestation of shock has as its outcome the conservation of body energy and fluid. I have found (Green, 1945) that if this mechanism be antagonized by raising the environmental temperature above a threshold value, there is no gradual onset of shock in the injured animal but instead, after an interval in which the animal remains lively, there is sudden collapse and rapid death. The state of anæsthesia has features in common with shock, though probably not a similar mechanism. Provided therefore that the secondary toxic effects are avoided, it may well be that anæsthesia may actually be beneficial in reinforcing a general defence mechanism to injury. Even if this hypothesis were true, it would not, of course, mean that clinical shock is a desirable state any more than high fever is. Clinical shock indicates large-scale tissue injury and any increase in this by anæsthetic overdosage and anoxæmia will, of course, accentuate the general reaction, bringing it ever closer to the so-called "irreversible state" in which the energy output of the body is so low as to be incompatible with recovery. Just so, high fever may of itself produce damage to the central nervous system incompatible with life. But up to a certain point shock, like fever, must be a beneficent reaction. Unfortunately, unlike fever, we have no accurate measure of the safety limit and therefore in practice it must always be regarded as a dangerous state. Nevertheless future work may ultimately modify this view when degrees of shock can be estimated.

It will be clear, however, that we do not treat shock as such any more than we treat fever as such, but rather that we treat the offending cause. Clinical shock is the expression of large-scale tissue injury and the treatment is solely that of restoring the injured parts to normal. If the exciting cause is loss of blood and/or body fluids and electrolytes we remove the cause by giving blood. If the cause be faulty anæsthesia the treatment is not transfusion but alteration in the anæsthetic technique. In the final analysis anæsthesia is the most potent weapon in the prophylaxis of shock we have, for with it damaged tissue can be removed or restored which would often otherwise remain to kill. Not being a practical anæsthetist, it would be presumptuous of me to give advice on the least harmful mode of anæsthesia particularly as it is obvious that all developments in technique have precisely this object in view. To me it would seem that modern anæsthesia at its best has largely attained this end by refinements of technique, giving always a free airway and accurately controlled dosage. As an outsider sees it, nitrous oxide and oxygen combined, when necessary, with other methods of producing relaxation, such as curare or local anæsthesia, seem to be approaching an ideal anæsthesia wherever shock exists or may threaten.

The anæsthetist ought to become the recognized expert in clinical shock. He has the best facilities for assessing the degree of shock by the established methods states, and, as we have seen, there are undoubtedly important common features. In established shock the two states reinforce each other and it may be useful to consider some possible explanations of how the presence of shock could affect the anæsthetic dose. One theory of anæsthetic action is that the reactivity of the nerve cell is reduced by interference with intracellular oxidation. This is also a feature of shock and thus theoretically the two states might summate. This is a rather ingenuous theory but there is a more practical connexion between the general depression of shock and anæsthesia. Diminished oxidation and enzymic activity will retard the breakdown of or conversion of anæsthetics into non-narcotic substances. The diminished blood volume will increase the anæsthetic concentration of the blood and, perhaps more important still, the damped-down kidney and respiratory excretion will maintain the tissue concentration at a relatively higher level than in the normal subject. Thus, though we do not know in what way anæsthesia and shock are precisely related, the view that they are supplementary rather than complementary states seems the more plausible. Whatever view we take, however, there is no lack of sound reasons for stressing the particular importance of anæsthetic overdosage in the shocked or potentially shocked patient.

It does not follow, as I have stressed, that, because the shocked individual requires less anæsthetic, anæsthesia necessarily predisposes to shock and, in fact, it would seem that the reverse hypothesis that, in its uncomplicated form, anæsthesia is in some degree protective against shock, has points in its favour. The surgeons who first used anæsthetics were impressed, in the light of their previous experience, by the diminished degree of shock during and after major operations. The difference in a conscious patient with a wound of the gut and an anæsthetized patient undergoing a major abdominal operation is striking. We are by no means certain yet that the rôle of sensory stimuli in the induction of traumatic shock is negligible. In spite of conflicting evidence it seems fairly clear that complete section of the spinal cord does not prevent and may well be dangerous in established shock. Nor is there any convincing evidence that spinal anæsthesia has any protective action and there is little doubt that it may be dangerous after experimental shock has been induced. But the evidence is not all in the same direction and one has always felt how unlikely it was that such a profound general response to injury would be completely independent of the nervous system. The reason for some of the contradictory findings may perhaps be found in the work of Swingle and his collaborators (1944). They found that shock in dogs could be prevented by effective procaine anæsthetization of the major nerves to the traumatized limb though section of these nerves was ineffective. Complete spinal section was also ineffective. However, when the cord was only partially sectioned in such a way as to leave tracts in the ventral area intact death from an otherwise lethal injury to the limb did not occur. If this work is substantiated then the conclusion must follow that afferent nerve impulses from the injured tissue have a shock-inducing effect. It would appear that the beneficial effect of removing these impulses is nullified if at the same time other nervous connexions with the injured area are severed. My own interpretation is that the absence of efferent nervous impulses increases local fluid loss by diminishing tone in the limb vessels, for Freedman and Kabat (1940) were able to prevent traumatic shock by a combination of spinal section and limb binding. It must be concluded provisionally that afferent nerve impulses do play some part in the whole complicated genesis of shock and therefore that local and regional anæsthesia have some place in shock prophylaxis. How important a part the nervous system plays must await further investigation for most workers have hitherto appeared to assume that there was only one major exciting factor in shock, overlooking the fact that shock is not a simple state but a complex integrated mechanism set in motion by a variety of stimuli.

Even if we disregard the rôle of sensory stimuli there are other theoretically

The changes in the fit young male adult from injury, through resuscitation to operation and finally to evacuation or death, depend upon a number of factors, which No. 1 Traumatic Shock Research Team under Dr. R. T. Grant set out to investigate during the late war in Italy. As the anæsthetist of the team it fell to my lot to examine the changes at operation and to see what part anæsthesia played in their production. I wish to thank Dr. Grant for allowing me to use the findings of the team in so far as they help in the elucidation of the problems of anæsthesia. This paper is based on some 63 limb and 60 belly injuries which were mainly observed by me and constituted only a part of the total material of the team.

In limb injuries the illness of the patient depends mainly upon hæmorrhage. This is very important. Further, the clinical estimate of blood loss is often considerably less than what is found by measurement of the blood volume. A patient may appear on clinical grounds to be reasonably fit a few hours after injury and yet he has lost as much as 40% of his blood. Such a patient may have a normal blood-pressure. In general blood loss after injury depends upon the amount of damaged tissue remaining adherent to the body. If this is correlated with the clinical signs a good idea of hæmorrhage can be gained.[1]

Briefly, the signs found at operation in limb injuries depended on blood loss. The greater the blood loss after injury and the smaller the amount of preoperative transfusion the paler the face, the more the tachycardia, the lower the blood-pressure and the more intense the vasoconstriction. By this last was meant cold exposed finger tips, constricted veins, a narrow width of radial pulse and a pale skin.

In belly injuries the same was true but to a lesser extent. Tachycardia and hypotension were present in patients who had not lost much blood and had been over-transfused and who had a general peritonitis.

Other factors caused an alteration in the signs at operation. Pressor and depressor blood-pressure responses were observed in both limb and belly cases with either an increase or a slowing of the pulse-rate at the time of surgical manipulations, although these were not infrequently performed without any immediate change. Previous blood loss enhanced the depressor response. (In one case traction on the guts in the presence of a general peritonitis resulted in a sudden fall in blood-pressure and a slowing of the pulse-rate and the immediate death of the patient. Vasovagal type of response.)

Sudden blood loss at operation was associated with a depressor change with either an increase or a decrease in the pulse-rate. The greater the hæmorrhage after injury and the more rapid the loss at operation the more obvious the effects of even a small amount. (One such case with a limb injury lost ½ pint of blood suddenly. Immediately the blood-pressure fell so as to be unrecordable, there was a marked slowing of the pulse-rate (axillary), a sudden decrease in the frequency and amplitude of respirations and a dilatation of the pupils.)

In the conscious state transfusion was associated with a rise in blood-pressure and this was also observed under anæsthesia.

Anæsthesia under certain circumstances was found to alter these signs and under others to add to them. What then are the effects of anæsthesia? Are there any adverse effects and what is the significance of these?

The evidence shows that there is often a pressor effect at operation which is due to the anæsthetic. At about the end of operation when the mask or endotracheal tube is withdrawn there is frequently an abrupt fall in blood-pressure. This is due to the anæsthetic because if the mask is reapplied the pressure rises. It falls again on finally removing the mask. This test was applied in 6 cases and a positive result obtained in all. The fall in blood-pressure is independent of surgical manipulations and he is most directly concerned with the degree of tissue oxidation and for these reasons he should be concerned with wider considerations than the anæsthetic itself. He ought to be aware of the profound prophylactic effects of adequate tissue hydration, since dehydration, due to the accumulation of fluid and sodium in the injured area, is, after frank loss of blood, probably the commonest exciting cause of shock. He should know of the detrimental effect of overheating, both local and general, and the beneficial effect of local cooling of injured parts. He should be acutely aware of the much lower tolerance to shock with advancing age and in the presence of infection. Particularly should he recognize that the shock mechanism takes time to develop as a clinical entity and that the apparently good subject on the table may have his tissues so damaged by the surgeon and anæsthetist combined that the resulting death from "bronchial pneumonia" [*sic*] is really only an expression of delayed shock. In civilized man, whose injuries can usually, in some degree, be modified by active intervention, it is, at the clinically detectable stage, always undesirable. Clinical shock means extensive tissue injury and in the present state of knowledge we can take no further risks.

Dr. R. P. Harbord: Lundy has recently said in relation to "shock".

". . . the patient may have suffered an injury and may have lost blood. He may have been exposed to a strong electric current. He may have become weakened by a long and debilitating disease and may have been bedridden for a long time."

The question "what is the best anæsthetic for shock?" is thus ambiguous if by "shock" is meant a number of different conditions.

The present confusion of thought is because of this lumping together of various illnesses. When certain signs of a similar character occur, the state is dubbed "shock" irrespective of the illness or injury concerned. It is the current teaching that "shock" may develop at operation when there is a falling blood-pressure and a rising pulse-rate. When the systolic pressure reaches 80 mm.Hg and the pulse-rate 100 per minute or more clinical "shock" is said to be also present.

It is not generally realized that the combination of these signs may, under different circumstances, have all the differences in significance as between life and death. The use of a term to describe them as a syndrome is therefore misleading. A study of the responses of a standard type of patient under similar conditions yields information of a more useful kind.

scription "a good colour" although it subsequently turned out from the calculations that these patients had lost considerable amounts of blood after injury and had had little transfusion. The rapid return of facial pallor after the cessation of the administration of anæsthesia shows that the colour of the face is an unreliable sign.

Because the patient is "pink, warm and dry" at operation we should not neglect the other signs (e.g. blood-pressure and pulse-rate) or forget to consider the type of injury. When the word warm is used this should be qualified in relation to what is warm because the extremities behave differently from other parts of the body and have a different significance. Sweating may be produced by weather conditions, by ether and results from disturbances of the administration of anæsthesia.

Certain additional points in relation to the signs at operation are of importance to the anæsthetist.

(1) A hypotension may develop without any change in the facial colour or in the temperature of the extremities.

(2) Estimations of the systolic level by the feel of the radial pulse are inaccurate. (In one case the radial pulse was not palpable at the wrist and yet a manometer showed a normal blood-pressure. In this case the weather was cold and vasoconstriction was present.)

It is therefore important to use a manometer for measuring blood-pressure. This should be estimated frequently (every five minutes) in any case in whom deterioration is likely to occur.

Hypotension at operation might be due to one or more of the following:

(1) Blood loss after injury with insufficient transfusion.

(2) Further blood loss at operation.

(3) Surgical manipulation.

(4) Anæsthesia.

The significance of this sign is varied according to its cause, for example, the hypotension due to blood loss responds to transfusion although this may be insufficient to replace the loss. Hypotension due to surgical manipulation disappears after the trauma has ceased, though it may be immediately fatal as with a sudden hæmorrhage.

Hypotension due to anæsthesia was most marked in the case of chloroform. In patients with minor injuries there is no reason why a certain amount of hypotension should be harmful. It will recover when the administration ends. With injuries of a more serious character it seems unjustifiable to contribute to the hypotension. The initial pentothal produced hypotension in a few cases only. Generally in the cases having pentothal as the sole anæsthetic such hypotension as was produced could be related to causes other than anæsthesia, e.g. blood loss.

Prolonged hypotension at or after operation in a belly case with general peritonitis is a grave sign for many of these patients die soon after operation in a state of tachycardia, hypotension and vasoconstriction. Prolonged hypotension at or after operation in a limb injury is a serious sign but the patient should recover if he is adequately transfused. Transfusion should be tried in the case of the hypotension which becomes revealed after disconnecting anæsthetic apparatus because this may be due to blood loss. The use of vasoconstrictors was in some cases followed by adverse effects and they appear to be of little value in the treatment of hypotension which is due to blood loss.

It should be seldom necessary to anæsthetize a patient with a limb injury with pallor, tachycardia, hypotension and vasoconstriction because properly treated such a patient ought to reach operation with a circulation well restored.

and occurs after cyclopropane, trilene or ether. A study of the clinical details in cases in whom it was well marked shows that it was most probably due to a change in the CO_2 stimulus from rebreathing to air.

Coincidental changes were found in the facial colour which became paler, in the pulse-rate which increased, in the temperature of the extremities which cooled, and also in the respirations which became shallower.

The extent of the fall in blood-pressure was in many cases slight but in some it was sufficient to cause alarm. The fall occurred irrespective of the level of systolic blood-pressure just before the removal of the mask. The change had in several instances been preceded by a gradually progressive rise in blood-pressure. In others the pressure had been falling and this was further accentuated.

The significance of the pressor effect is as follows:

(1) The blood-pressure is maintained at a spurious level during anæsthesia.

(2) A false interpretation is obtained concerning the state of the patient. (Judgment should be made after the mask has been removed and not immediately before.)

(3) The pressor effect may reflect an additional circulatory strain.

(4) The period immediately following the removal of the mask is potentially dangerous. If the fall in systolic pressure is marked it may be wiser to defer movement or refrain from any surgical manipulation for the time being.

Other effects of anæsthesia depended upon the drug employed. The following signs were recorded in the induction period:

(1) Pentothal: A fall in blood-pressure and a rise in pulse-rate.

(2) Chloroform: A fall in blood-pressure and a slowing of the pulse-rate.

(3) Cyclopropane: A variable effect on the blood-pressure which was not marked. A fairly constant feature was the slowing of pulse-rate which occurred less frequently in those who had lost considerable amounts of blood.

(4) Ether: The effects of ether were so distorted by disturbances of the administration of anæsthesia and by the effects of other drugs used in the induction (ethyl chloride, nitrous oxide or pentothal) that it was almost impossible to observe the precise changes due to this drug. In uncomplicated cases there appeared to be but little effect.

These changes were found in both limb and belly cases. The effects of the drugs on the blood-pressure were more difficult to assess once the induction had passed because of surgical manipulations, blood loss and disturbances of the administration of anæsthesia. There was a general tendency which was more marked in the limb cases for the blood-pressure to decline progressively through operation. In spite of this tendency certain cases showed that ether anæsthesia could be prolonged for as long as two hours without the production of a hypotension.

With pentothal anæsthesia in the limb injuries there was but little alteration in the facial colour or in the temperature of the exposed extremities. With ether and cyclopropane, on the other hand, the face was frequently a deeper colour at operation and the extremities became warmer (sometimes hot), and the radial pulse wider, the veins dilated and sweating occurred, especially with ether. There was thus a well-marked vasodilatation. The flushing of the face was probably partly related to the constricting effect of the mask harness. At any rate the patient appeared to be relatively *unchanged* as judged by the facial colour with pentothal, whereas with ether or cyclopropane it looked as though his condition had improved. This "improvement" was more apparent than real. Since it is a change which is imposed upon the patient by anæsthesia it may in fact be an adverse effect. In some cases the face became sufficiently well coloured at operation to merit the de-

Pentothal had certain advantages in cases with limb injuries, e.g. an adequate depth of anæsthesia could be attained rapidly, disturbances of the administration were less, and there was less alteration of the signs of blood loss at operation. For belly injuries cyclopropane or ether after various methods of induction was found to be satisfactory if administered without disturbance. In some cases the combination of regional blocks and general anæsthesia appeared to be ideal.

Anæsthesia tends to alter the signs in the patient which have resulted from injury and hæmorrhage by pressor effects with vasodilatation. At times the initial response from anæsthetic drugs add to the signs already present. The alteration of the signs is less well marked in those who have lost considerable amounts of blood. If the patient has facial pallor, tachycardia, hypotension and vasoconstriction before the induction of anæsthesia it is probable that most of these signs will remain through operation though some may be slightly modified.

The final outcome; recovery or death, in limb injuries depends on blood loss and its treatment. In belly injuries it depends on blood loss in some cases but since a good many die of peritonitis the outcome rests with surgery.

The following points are worthy of stressing in relation to anæsthesia. Pay particular attention to the administration. Obtain a sufficient depth and do not hope for this with fantastically small amounts of the drug. Once the depth is attained maintain it with whatever is necessary. Induce anæsthesia with the head low and be ready to treat the patient who vomits.

Watch the signs carefully, particularly the blood-pressure. Hypotension may be a sign of considerable hæmorrhage. Its absence does not necessarily mean that all is well and its return to normal with transfusion does not mean that this has been sufficient. The signs in a patient should never be considered alone but in relation to his injuries and the possibility of blood loss or peritonitis. When referring to deterioration at operation we should state exactly what we mean.

I should like to thank Drs. Grant and Reeve for their constant encouragement; Dr. Daly for making available such equipment as I required; and Drs. George Edwards and Bernard Johnson and Lieut.-Colonel Scriven for advice and help.

Dr. R. J. Minnitt mentioned some research work on shock and anæsthesia which he had carried out in 1924-25. This formed the basis of a paper he read before the Section of Anæsthetics in 1932 (*Proc. R. Soc. Med.*, 26, 347). It showed that during open ether anæsthesia, when shock symptoms appeared, blood-pressure was low and blood sugar high. After the operation was over the blood-pressure rose again, and the blood sugar fell. He asked Dr. Harbord whether he had any information of blood-sugar estimations in his series of cases.

Dr. Minnitt also suggested that the reason why blood-pressure findings were low after operation in the cases described by Dr. Harbord was owing to the method of anæsthesia having been a semi-closed or closed one.

Dr. Ronald Woolmer asked whether—in view of the concept of shock as acting to some extent protectively by conserving body energy, and in the light of what we knew of the beneficial effects of local cooling—the practice of applying artificial heat in shock, which was regarded as one of the cardinal principles of treatment, should be modified.

He thought that the fall in blood-pressure which occurred with high spinal analgesia was similarly protective, and his impression was that the end-results were at least as good if no attempt were made to raise the blood-pressure by the injection of vasopressor drugs. He thought there was an analogy between the application of artificial heat in cases of shock, and the artificial raising of the blood-pressure in spinal analgesia.

Dr. Barnet Solomons: In battle casualties in a jungle sector it was noted that crush and bullet injuries of the foot led to excessive shock in comparison with injuries of a greater degree in other parts of the limbs. Shock was surprisingly slight in severe injuries of the face and neck, even with much mutilation and tissue loss.

2 to 5 c.c. of pentothal in 2½% dilution was invaluable as an analgesic in anxious shocked casualties, to promote rest and quiet, and to enable a drip to be set up with ease. No further anæsthetic was administered until the general condition showed improvement

It has been stated that the "shocked" patient is very susceptible to anæsthetic drugs. The doses of these in the patients with limb or belly injuries were what would have been expected in normal patients undergoing similar operations. When the dose was deliberately reduced the depth of anæsthesia was either frankly inadequate or barely sufficient. This is contrary to what would have been expected in patients who had lost as much as 40% to 60% of their blood and had generally received insufficient transfusion. I have not witnessed operations on patients who were known to have sustained losses of more than 65% of their blood.

Of the whole series of 123 cases two belly cases died while still upon the operating table as a direct result of anæsthesia. Unfortunately I did not witness either of these cases.

The first patient had a lacerated ileum which was twenty-seven hours old. He had a general peritonitis. He became cyanosed while breathing a 4:1 nitrous oxide oxygen mixture and appeared to be deep one moment and light the next. Respirations appeared to be free but cyanosis persisted and he died in spite of intubation and artificial respiration ten minutes from the beginning of anæsthesia. Surgery had not begun. At autopsy vomit was found in the trachea and main bronchi. If this had occurred at operation it would have accounted for the cyanosis and may have contributed materially to his death.

The second patient had a large retroperitoneal hæmatoma and a bruise of the colon and he should have recovered. Anæsthesia was complicated by respiratory obstruction over a long period and the depth was not adequate. It took the surgeon seventy-two minutes to close the peritoneal cavity. The patient died about two hours from the beginning of anæsthesia. The clinical signs during most of the operation were tachycardia, hypertension, vasodilatation and sweating. The face was well coloured but was deeply cyanosed for a long time.

Disturbances of the administration of anæsthesia were frequent and were either unobserved by the anæsthetist or disregarded. Some of the 20 anæsthetists who were observed were reasonably skilful. Respiratory obstruction or hypercapnia was associated with pressor effects on the blood-pressure and vasodilatation.

Numerous examples could be quoted of cases who appeared to have some obstruction to respiration. It was especially frequent during the induction of anæsthesia and was least common with pentothal anæsthesia. In some cases it was obvious but in others insidious. The diagnosis is only certain when the respiratory movements increase at the expense of the tidal volume. Obstruction was often produced reflexly by a surgical stimulus under light anæsthesia.

Vomiting was observed during operation in 8 cases, 4 of which were limb and 4 belly cases. Pentothal anæsthesia was in progress in 6 of the cases. Vomiting was sometimes insidious, that is, it occurred without any visible expulsive effort. There were other cases which I have not included amongst the 8 who vomited at operation, e.g. 12 out of 17 pharyngeal packs used with endotracheal anæsthesia were contaminated with a fluid having the appearances of gastric secretion. Vomit sometimes produced respiratory obstruction either by setting up laryngeal spasm or by accumulating in the trachea. In one case a pulmonary abscess was aspirated about a week after operation which was related to vomiting and respiratory obstruction during anæsthesia. Other cases had pulmonary complications which appeared to be due to vomiting at operation. One case (who has not been included in the series) was witnessed who died in the induction of anæsthesia with pentothal as a direct result of vomiting and aspiration.

So frequent were these disturbances of the administration of the anæsthetic that it appeared that skill in the administration was more important than the choice of anæsthetic when comparisons were made between pentothal, ether or cyclopropane.

Section of Proctology

President—A. HEDLEY WHYTE, D.S.O., T.D., M.S., F.R.C.S.

[*November 20*, 1946]

Proctology Past and Present

PRESIDENT'S ADDRESS

By A. HEDLEY WHYTE, D.S.O., T.D., M.S., F.R.C.S.

THE dawn of the history of medicine takes us a very long way back, how far has always been in some doubt. Such authorities as Clifford Allbutt and William Osler think no further back than early Greek and Roman civilizations. The former wrote: "The medicine of Egypt and the East, extensive and intricate as it was, in so far as it is not Greek, does not contain even the rudiments of science." Sir William Osler wrote similarly: "Crude and bizarre among the primitive nations, their ideas of disease received among the Greeks and Romans a practical development worthy of these peoples. There have been systems of so-called divine healing in all the great civilizations, but for beauty of conception, and grandeur of detail in execution, all are as nothing in comparison with the cult of the son of Apollo, and of Æsculapius, the god of healing."

"Scientific medicine, the product of a union of religion with philosophy, had its origin in a remarkable conjunction of gifts and conditions among the Greeks in the sixth century."

"Facts regarding the ancient history of medicine have been sought for only in the classical authors of Greece and Rome, and have been arranged to suit a traditional theory which repudiated all systems which did not proceed from a Grecian source. We are familiar, from our youth, with classical history, and we love to recall events illustrated by the torch of Genius, and depicted in our memories."

But still candour and truth require us to examine new facts in history as they are discovered, and we must try and arrive at just conclusions.

In what has modestly been termed a monograph, published in Calcutta in 1913 [1], there is a wonderful description of old Hindu surgical instruments, with a comparative study of the Greek, Roman and Arab surgeons with the surgeons in modern times. There is little doubt that Indian medicine was advancing from consisting merely of spells and incantations against the demons of disease.

In 226 B.C. King Asoka [2] records the erection of hospitals by him, and Cingalese records indicate the existence of hospitals in Ceylon as early as 437 B.C.

One of the great Brahminical works is the Susruta (fifth century A.D.), a great storehouse of Aryan knowledge. Susruta recommends lotus leaves and plantain leaves as coverings to bleeding piles, and also the application of caustics to them. If these measures were not efficacious then he applied horse-hair ligatures round the piles. There are reasons for thinking that, contrary to the oft-expressed opinions of our betters, Greek medicine and thought may really have been founded on the more ancient Hindu medical doctrines. We know Alexander was not satisfied with his own Army surgeons, and had to take several Indian ones on to his Staff. These later he took back to Greece with him, and, in this way, there is every possibility that their knowledge and practice might have germinated in their new country of adoption.

So much for the ancient period which ends with Galen (131-202) who explained all in the light of pure theory, and such was the effect of his dogmatism and infallibility, that European medicine remained at a dead level for nearly fourteen centuries.

Dr. H. W. Loftus Dale said he would be interested to hear what observations the openers had to make concerning two techniques which had not been mentioned, refrigeration anæsthesia and curare.

He had, himself, used the former on five occasions for amputations of the lower limb in very poor risk cases, and had been impressed by the fact that there had been little or no alteration in pulse or blood-pressure, and no further deterioration in the patient's general condition, trauma to the great sciatic nerve had produced no noticeable effect.

Concerning curare, he would be interested to learn if there was any explanation for the fact that severe operations such as abdomino-perineal excision of the rectum and partial gastrectomy could be performed in light planes of general anæsthesia with the help of curare—which produced no sensory loss—without the production of shock.

Dr. Stanley Rowbotham (President) thanked Professor Green and Dr. Harbord for their valuable papers; shock was a condition which the anæsthetist encountered only too often, and about which he could never learn too much. To-day they had gained a great deal of very valuable knowledge.

He agreed with Professor Mackintosh that " In shock a little anæsthetic goes a long way". He well remembered the case of a wounded German soldier with advanced peritonitis who died after receiving only 1 c.c. of 5% pentothal.

He had been greatly impressed by intravenous procaine in cases of severe burns, which he had seen used by the Canadian Medical Corps during the war. He had himself given it to two cases; both were rendered free of pain within about five minutes and the pulse straightway improved.

Dr. R. P. Harbord, in reply to Dr. Minnitt, said that the blood sugar had not been estimated in the cases under review. To Dr. Loftus Dale he said that he had no practical experience of refrigeration anæsthesia but that he could produce evidence of deterioration at operation when curare was used. To those who felt that "in shock a little anæsthetic goes a long way" he said that it all depended on what was meant by the word "shock". If a patient was on the brink of death it might be that the slightest push would send him over but it should be rare to have to anæsthetize such a patient.

Professor H. N. Green, in reply to Dr. Woolmer, said it was becoming more widely recognized that artificial heat, as a general rule, was not desirable in the treatment of shock. A physiological concept of shock would suggest that the body temperature should be allowed to reach its own level without artificial aid in either direction. From this point of view general cooling might be just as harmful.

To Dr. Loftus Dale he said, that from the experimental standpoint, refrigeration anæsthesia for amputation of the lower limb should be ideal. If shock in such cases were in a broad sense metabolic in origin local cooling would have a pronounced retarding effect on such changes, and also prevent the release into the general circulation of any metabolic factors formed.

If, in fact, shock did not occur with curare and light general anæsthesia it would be in line with the experimental evidence showing that, with an intact spinal cord, uncomplicated sensory nerve stimulation did not produce shock. Evidence was accumulating that stimulation of motor nerves might induce the metabolic changes associated with shock and I am now investigating whether curare has any prophylactic effect in experimental shock.

were being founded everywhere. Major surgical operations were being attempted, and to mention two examples, in 1808, an inter-scapulo-thoracic amputation was performed, and the first ovariotomy in 1809.

Fortunate in the time of his birth, was one Frederick Salmon, destined to be the father of proctology, and the founder of such a unique and famous hospital. Salmon was born in Bath in 1796. He received his medical education in St. Bartholomew's Hospital, and in 1827 he was elected surgeon to the General Dispensary in Aldersgate Street. He early interested himself in rectal diseases, and in 1835, in spite of a good deal of professional opposition, he acquired premises at 11, Aldersgate Street. This was "The Infirmary for the Relief of the Poor Afflicted with Fistula and Other Diseases of the Rectum".

Salmon was a great man who did great work. For twenty-two years he did the surgery of the hospital single-handed. Nine years after the hospital opened, he acquired a medical colleague, one John James Furnivall.

In 1838, a move was made to Charterhouse Square, and this meant the number of beds was doubled. In 1854, on St. Mark's Day, April 25, the hospital on the present site in City Road was opened with at first 25, and five years later, 30 beds. In 1927, the hospital was still further extended.

Three years after the move to City Road, Salmon was assisted by James Robert Lane and Peter Yeames Gowlland, and, in 1859, Salmon retired full of honour, and well beloved by all. He left for proctology, a great name, a great hospital, a book, his "Practical Treatise on Stricture of the Rectum", and his ligature operation, so well described by William Allingham in his textbook "Diseases of the Rectum" (1888).

Lane and Gowlland followed Salmon—Lane only stayed at St. Mark's 11 years. Meantime he had been appointed one of the original members of St. Mary's Hospital, and been unfortunate enough to develop locomotor ataxia. We read that in the prime of his life, and when a career of prosperity appeared to be within his grasp, he was stricken with this painful malady. In spite of being attended by agonies, which at times rendered his condition almost unendurable, he worked at St. Mary's until 1881.

This mid-Victorian era was a golden one for surgery, and I trust, surgeons too. We must always orientate our thinking in this period of surgical history around 1867, when Lister [9] published his article in the *British Medical Journal*, "On the Antiseptic Principle in the Practice of Surgery", remembering also the discovery of general anæsthesia some twenty years earlier.

It was an era with great surgical masters, and as early as 1844 Lee and Hay had successfully resected a part of the sigmoid colon for cancer. There were no further successes until the 1870s, when German surgeons adopted Lister's antiseptic technique, and began to attempt all sorts of formidable operations within the abdomen. Several of them shortly attempted to resect cancers of the colon, but probably the first to succeed was Vincent Czerny, Professor of Surgery at Heidelberg [10].. After several failures, he brought a patient through the procedure alive in 1879. By 1884 a total of 18 such operations had been done with 8 fatalities. The next generation saw great improvements in the technique of bowel resection. The really important advance came, however, with experimental studies carried out on dogs by William S. Halsted at Johns Hopkins Hospital. In 1887, in a series of careful experiments, he proved that the essential point in suturing the bowel is to include the submucous layer of the intestinal wall in the suture.

The surgical problem of cancer of the rectum is a more difficult one. Jacques Lisfranc, a brilliant Parisian surgeon of the Napoleonic period was the first in 1826 to excise the rectum for cancer. His resection, however, was of very limited extent, Oribasius [3] was another writer with an enormous amount of literature associated with his name. He was friend and physician-in-ordinary to Julian the Apostate in Constantinople, and was chiefly responsible for establishing Galen in his central position of authority during the Dark Ages.

Oribasius was a great compiler, and he twice mentions piles, suggesting that when treating them, one pile should always be left, otherwise the consequences might be dangerous. It is interesting to think how to this day a sort of feeling of security may be had by a patient with a bleeding pile. One often hears expressed the remark that it may be a safety valve against apoplexy, or, better have bleeding there than in the brain. Also too, there may be a lurking suspicion of dignity and aldermanic pomp associated with piles, and certainly often they enforce a steady, measured gait. With one or two exceptions, the medical world seems to have gone to sleep for centuries after Galen, and Osler has said: "From Hippocrates to Hunter, the treatment of disease was one long traffic in Hypotheses."

I would say it is a long stride from ancient Greece to a "small room in Aldersgate Street." [4]

In our jet-propelled flight through darkness, we notice *en passant*, only an odd proctological happening, a flash in the pan, as it were.

The greatest of the Moslem physicians of the Western Caliphate was the Cordovan Avenzoar [5], who died at Seville in 1162. He discovered the *Acarus scabiei*, was a great physician, and a great man. He cared nought for Galen, and it is interesting to know that he gave nutrient enemata to his patients with carcinoma of the stomach, and for those with carcinoma of the œsophagus, he passed a hollow metal tube through the growth, and through the tube he fed his patients on milk, eggs and gruel. When giving rectal feeds, he first washed out the lower bowel, and then he filled a goat's bladder, fastened a tube to it, and having inserted the tube into the rectum, the goat's bladder was emptied by compression.

The story of John Aderne of Newark is well known, thanks to the researches of D'Arcy Power and the Wellcome Research Institution. You have all seen the pictures of the fistula being split up. That was in 1376, and you have all read Gordon-Watson's delightful address, which he gave at St. Bartholomew's in 1934. If perchance there is anyone in this audience who has not read Sir Charles' "Progress in Rectal Surgery" [6], then he has a treat in store. Aderne's "Principles and Practice" must have soon been forgotten, for our Henry V died of fistula only forty-six years after Aderne's classic operation, because, we are told, "the surgeons had not the skill to cure." Rectal surgery, indeed all surgery, continued to occupy a very lowly position until the early part of the last century. Except for the famous operation by Félix on Louis in 1686 [7], and Percival Pott's treatise on fistula in 1765, there is little to make us pause. We want to get on and hear about St. Mark's, but I must first tell you the story about Félix and Louis XIV. At that time, French surgeons were little thought of by their more superior medical brethren, and all were more or less looked on as social inferiors.

Molière's comedies abounded in pungent raillery and light-barbed sarcasm directed with unerring skill against the tribe of doctors. In 1657, as luck would have it, when doctors were so little thought of, Louis had an attack of typhoid. He was treated with antimony and he recovered. This recovery raised the status of the profession in France, and also caused an immense vogue for the use of antimony. Six years later, his mistress was attended by the Royal accoucheur, a man, and this event did much to further the cause of male midwifery.

Louis' recovery from his attack of typhoid, and the successful delivery six years later by an obstetrician, much as these events tended to increase the standing of the profession, within the profession, the relative standing of the surgeons tended to be lowered by comparison, but in course of time they had their opportunity. In 1686, Félix opened up the King's fistula. The King was cured, and surgical times changed. Félix received six thousand pounds as a fee, and, what some of us might now think a very suitable refresher, he was also given a present of a farm. Félix was ennobled, becoming Seigneur de Stains. All his helpers received financial recognition in proportion. Félix was followed by Mareschal. Fistula became fashionable, and this, together with the exertions of Mareschal, put French surgery into the foreground.

Littré in 1710 first proposed colostomy for the relief of imperforate anus, but it is doubtful whether he ever performed the operation.

In 1776, Pillore of Rouen performed cæcostomy in the right iliac region for the relief of obstruction in an adult case, and four more cases were recorded before the end of the century, three for imperforate anus, and one of transverse colostomy. The transverse colostomy was inadvertently performed when a laparotomy was being done, with the intention of opening the small bowel.

In 1797, one Pierre Fine [8] (1760-1814) performed colostomy for intestinal obstruction in an adult, and we read that the patient survived for three and a half months.

The surgical dawn seemed to be breaking, and it is interesting to recollect that our College obtained its Royal Charter in 1800. Truly the early years of the last century saw great surgical and academic advances. Universities and hospitals

Goodsall certainly left his mark on Surgery, and his co-author, of course, has already done so. We know so much about Ernest Miles, but some of us perhaps do not know enough about Goodsall. His early life was hard. His father had died of a post-mortem wound infection when he was a student at St. Bartholomew's. and Widow Goodsall was left with four sons unprovided for. From the age of 14, D. H. kept himself and was apprenticed to a chemist at Aldgate. In view of his father's misfortune, St. Bartholomew's took him in, and he was allowed to pursue his medical studies, without having to pay any fees. He became in time a house surgeon at St. Mark's, and later surgeon there and at the Metropolitan Hospital. He recognized post-anal dermoids [13], and knew how to treat them by completely laying all the tracks open, whereas previously it had always been supposed they were a bone infection. It was John Bland-Sutton, of course, who told of their true nature, and Percy Lockhart-Mummery [13] who taught us to excise them completely. Mention of Miles naturally necessitates mention of Lockhart-Mummery. Since the turn of the century, what controversy raged about the adequate treatment of rectal carcinoma. Hartmann in Paris we associate with abdominal excision.

Many surgeons, the masters at St. Mark's and all over the world, were doing more and more and larger excisions. In Newcastle, Rutherford Morison, and later George Grey Turner, and in Rochester, the Mayos. The list is wellnigh inexhaustible. Great progress was made, but in January 1907 [14], Ernest Miles did his first abdomino-perineal excision, one of the most formidable operations in surgery. Miles described the operation, and explained what we now take so much for granted, the three zones of spread.

Miles ascribed an abdomino-perineal excision to Czerny in 1884, and after that to many others—Maunsell, Gaudier, Gant, Tuttle, Reverdin, Sir Charles Ball, Wallace and Aldrich-Blake—but it was not until he had thoroughly worked out the methods of spread that Miles was able properly to plan his operation similar in conception to Halsted's radical excision of the breast, and Wertheim's excision for uterine cancer. As Miles says with just pride in his "Rectal Surgery" in 1944: "The operation reduced the recurrence rate from 90% to 20%." It must surely be more than coincidence that the article directly in front of Ernest Miles' is by one Lionel Norbury. He was then a Registrar at St. Thomas's Hospital, and the article was on "A case of ruptured small intestine". The abdomino-perineal excision done by others than Miles had a very high mortality, and abdominal resections were favoured by Harrison Cripps (1907) and William Mayo (1912), and again by Hartmann in 1923. Lockhart-Mummery, except for high growths, always favoured an extended operation through the perineum.

George Grey Turner [15] in 1920 described a two-stage perineo-abdominal excision, and, in 1931, his classic Murphy oration on conservative sacral excision revived interest in less extensive operations than that of Miles'. Miles, however, won the day. As our mortality rates decrease as the result of experience, better technical understanding, better anæsthesia and modern resuscitation, more and more extensive excisions are performed. Well I remember the times when I used to assist my colleague and assistant chief, the late much-lamented Hamilton Drummond, and how gratified we were when the patient survived. Now, of course, a fatality is cause for comment, and perhaps recrimination. Gabriel's reverse method [16], and the synchronous combined operation described by O. V. Lloyd-Davies in 1939 [17] have largely taken the place previously occupied by Miles' operation. The advantages of the synchronous procedure so well detailed by Norbury in his Hunterian Lecture in 1941 are: (1) No necessity for moving the patient after he is once fixed in the required position. (2) The time taken over the operation is considerably diminished. (3) Growths adherent and which by other means would be considered inoperable may be successfully removed. (4) In selected cases a conservative recarried out through the perineum. The scope of this perineal resection was gradually extended after antiseptic surgery made extensive operations safer. In 1885, Paul Kraske, Professor of Surgery at Freiburg, introduced a method in which a portion of the sacrum was removed to give better access. The operation was widely used for more than a generation. Unfortunately, it had the same defect as other exterior or perineal operations for rectal cancer. The recurrence rate approximated 90%.

During this great time going forward with the great surge, we can imagine William Allingham, Alfred Cooper, David Henry Goodsall, F. Swinford Edwards, Herbert William Allingham, Frederick Charles Wallis and Percy Furnivall working away at St. Mark's. They all made their marks, some deeper than others, and all left "Marks" better for their passing that way.

Piles, fistulæ, fissures, prolapse, stricture and carcinoma. What discussions there were. We have the classical papers of William Allingham on the treatment of fistulous sinuses by the elastic ligature, on inguinal colostomy and piles.

Sir Alfred Cooper's classic on inflammation of the rectum, D. H. Goodsall's papers on foreign bodies in the rectum, six cases of sinuses over the sacrum and coccyx and on fissure all these, and many more equally interesting and instructive, are preserved and beautifully presented for us in the St. Mark's Centenary Volume.

Take the subject of colostomy alone—colostomy or colotomy—the varieties thereof, and the technicalities of the operation.

As mentioned before, Pierre Fine had performed colotomy in 1797. Three more were done in 1814, 1817 and 1820.

Between 1839 and 1841, Amussat [11] wrote and popularized lumbar colostomy. His first cases were on the right side, and the opening made into the ascending colon. As time went on, many cases were reported, many more in this country than in the United States of America, where there was considerable opposition to the operation. Gross in his "System of Surgery" apologizes for even mentioning the operation.

During this time Paul was practising in Liverpool and perfecting his classical exteriorization and Mikulicz was trying to extend its usefulness in Vienna.

The injection treatment of piles [12], which had so long been frowned upon by the orthodox, was being tried out more and more. In the United States of America in 1836, Long injected sulphate of iron into a nævus. In 1869 Morgan in Dublin tried the same treatment with hæmorrhoids, and in 1874 Colles used perchloride of iron. In 1871 Mitchell of Colindale in Illinois had first used carbolic acid in two parts of olive oil. As the result of his method becoming known, he apparently became so busy that he could not attend to all his patients, and, it must be noted with regret, he sold his secret prescription. As our present Minister of Health might say, there was a "rash" of pile injectors all over the country. With the orthodox, the method, therefore, fell into disrepute, but later was revised by Andrews of Chicago and others. The strong solutions gave way to weaker ones with more satisfactory results.

After the early 1800s had seen such great surgical progress, so were the last years of the century to witness equally epoch-making advances. Towards the end of the century, Goodsall, whose name to this day is associated with his line and his stitch, was writing his book. He was assisted in his literary endeavour by a young surgeon who had been a house surgeon at St. Mark's, and who was then assistant surgeon at the Cancer Hospital, and surgeon to outpatients at the Gordon Hospital. What a wonderful combination, David Goodsall and Ernest Miles. Their book was published in 1900, with a second edition published in 1905, which contained a classical article on colostomy. They also well described the operations for rectal cancer being done at that time.

Studies on the Hæmatology of the Horse, Ox and Sheep

By H. H. Holman, D.Sc., Ph.D., M.R.C.V.S.

Early workers in veterinary hæmatology all appear to have concentrated on determining the correct average for the different constituents of blood, and even as late as 1935 one writer, in a review article, used the results obtained by several investigators in an attempt to standardize averages for such estimates as the erythrocyte counts for farm animals. This worker considered that 6·6 million erythrocytes per c.mm. could be accepted as the true average for the ox but, unfortunately, this knowledge is of little value to the clinician or the experimental pathologist in deciding whether a cow with a count of only 5 million should be accepted as normal or should be considered as suffering from some degree of anæmia. Therefore in clinical work and experimental work, what is important is not the average but the normal range for the healthy animal; and that is where veterinary literature gives one so little help.

Early investigators usually employed small groups of animals all in the same flock or herd and restricted their results to the average, or the average together with the maximum and minimum—that standard that Yule has called "The worst of all possible measures for any serious purpose"—and to explain their results it is to be feared that in some cases figures that seemed to fall at too great a distance from the mean were omitted as due to "experimental error".

The result of such omissions is reflected in those textbooks and articles that publish the averages for the various counts as the normal for various animals but stipulate that figures within 10% on either side may be accepted as samples from healthy animals. The work of Berkson, Magath and Hurn (1940) and of Berg (1945), has confirmed that even in the red count, where the error is less than in either the absolute or relative leucocyte count, the distribution error alone can easily account for ± 10%. Thus, admitting only counts within 10% of the means as normal, it should be quite possible to show some animals to be suffering from anæmia one day and anhydræmia the next or to show that most healthy animals varied from leucopenia to leucocytosis several times a week.

In this country the first real attempt to establish the normal range for the sheep and the ox by using the standard deviation was made by Fraser (1930), but unfortunately his efforts were restricted in numbers and with regard to season and environment. Nevertheless he showed that variation between healthy animals was extensive and established a paradox by showing that improved mathematical interpretation widened, rather than narrowed, the normal range.

Histograms for sheep sampled between June and December show the wide distribution; the red count varies from a class with a centre point of 6·5 to one with a centre point 15·5 million per c.mm. The distribution of the white count is remarkably irregular, varying from the 2,000 class to the 14,000 class with one animal isolated at 18,000 per c.mm. Eosinophils and basophils are both skewed to the right, in fact basophils show the mode at zero.

We know that with worm infestation there is a neutrophilia, an eosinophilia in benign cases and a tendency to anæmia, so that when we see that the distribution for both neutrophils and eosinophils is skewed to the right and that for hæmoglobin is skewed to the left, it does suggest that although we begin by choosing apparently healthy animals to record their blood picture, we can end by using the blood picture to suggest that many of these animals were not healthy. In spite of this there appears to be no remedy, for it is the animal free from worm infestation section of the recto-sigmoid is rendered easier. These advantages make this method the one of choice with most modern surgeons.

Personally I have a sneaking affection for what I call my extended Hartmann which is an abdomino-perineal, which stops short, as it were, and preserves the perineum. I don't believe in the downward spread, but that can wait for another time.

Modern resuscitation methods have been mentioned. You all know Officers apparatus. "An important and erudite contribution on the physiology of water balance and the problems associated with the administration of fluids" is how Gabriel rightly describes Avery Jones and Naunton Morgan's article in St. Bart's Hospital Reports in 1938 [18]. With our facilities, all we want is our patients earlier. The outlook in rectal carcinoma becomes better each year, and who knows what advances lie ahead. We remember Gordon-Watson's enthusiasm in the late twenties with radium, and how we followed him, and like him, were disappointed; but perhaps the physicists may have something to give us soon.

Mention must be made of Milligan's pile operation [19], correct anatomically, and a great advance on Salmon, Smith and Whitehead. Also we are indebted to Milligan and Morgan for their anatomical work [20] and their classification of fistula.

Purposely I have kept till the last my tribute to Cuthbert Dukes. His work since 1922 at St. Mark's on all problems connected with the pathology and biochemistry of rectal disease is known the world over. His apparatus for the post-operative collection of urine is universally used. He has elucidated the relationship of simple tumours to intestinal cancer. His work on rectal stricture rivals Bensuade's in importance, and, with Broder's classification of malignant tumours based on the principle of cell differentiation, his method of classification by extent of spread has enabled us scientifically to grade and classify our cases.

Studies on the Hæmatology of the Horse, Ox and Sheep

By H. H. Holman, D.Sc., Ph.D., M.R.C.V.S.

Early workers in veterinary hæmatology all appear to have concentrated on determining the correct average for the different constituents of blood, and even as late as 1935 one writer, in a review article, used the results obtained by several investigators in an attempt to standardize averages for such estimates as the erythrocyte counts for farm animals. This worker considered that 6·6 million erythrocytes per c.mm. could be accepted as the true average for the ox but, unfortunately, this knowledge is of little value to the clinician or the experimental pathologist in deciding whether a cow with a count of only 5 million should be accepted as normal or should be considered as suffering from some degree of anæmia. Therefore in clinical work and experimental work, what is important is not the average but the normal range for the healthy animal; and that is where veterinary literature gives one so little help.

Early investigators usually employed small groups of animals all in the same flock or herd and restricted their results to the average, or the average together with the maximum and minimum—that standard that Yule has called "The worst of all possible measures for any serious purpose"—and to explain their results it is to be feared that in some cases figures that seemed to fall at too great a distance from the mean were omitted as due to "experimental error".

The result of such omissions is reflected in those textbooks and articles that publish the averages for the various counts as the normal for various animals but stipulate that figures within 10% on either side may be accepted as samples from healthy animals. The work of Berkson, Magath and Hurn (1940) and of Berg (1945), has confirmed that even in the red count, where the error is less than in either the absolute or relative leucocyte count, the distribution error alone can easily account for ± 10%. Thus, admitting only counts within 10% of the means as normal, it should be quite possible to show some animals to be suffering from anæmia one day and anhydræmia the next or to show that most healthy animals varied from leucopenia to leucocytosis several times a week.

In this country the first real attempt to establish the normal range for the sheep and the ox by using the standard deviation was made by Fraser (1930), but unfortunately his efforts were restricted in numbers and with regard to season and environment. Nevertheless he showed that variation between healthy animals was extensive and established a paradox by showing that improved mathematical interpretation widened, rather than narrowed, the normal range.

Histograms for sheep sampled between June and December show the wide distribution; the red count varies from a class with a centre point of 6·5 to one with a centre point 15·5 million per c.mm. The distribution of the white count is remarkably irregular, varying from the 2,000 class to the 14,000 class with one animal isolated at 18,000 per c.mm. Eosinophils and basophils are both skewed to the right, in fact basophils show the mode at zero.

We know that with worm infestation there is a neutrophilia, an eosinophilia in benign cases and a tendency to anæmia, so that when we see that the distribution for both neutrophils and eosinophils is skewed to the right and that for hæmoglobin is skewed to the left, it does suggest that although we begin by choosing apparently healthy animals to record their blood picture, we can end by using the blood picture to suggest that many of these animals were not healthy. In spite of this there appears to be no remedy, for it is the animal free from worm infestation that is an abnormal farm animal, and if one is to restrict sampling to such abnormal animals, the clinical value of the result is negligible.

The wide range for most constituents in farm animals, although it permits one to judge a flock or herd of animals, is useless in judging small changes in the individual animal. If, therefore, we are interested in experimental pathology, we must try to devise some criterion for limiting the normal range as regards an individual; this I have attempted to do by introducing what Dr. Kermack of Edinburgh—who was kind enough to help me—termed the Maximum Admissible Difference.

This parameter is obtained by bleeding animals at the same time on two consecutive days and finding the difference for each constituent. These differences are used to calculate the standard deviation and the table of "t" is then used to find the area covering 95% of the possibility. Thus the M.A.D. for the daily variation in the red count is rather less than ± 3 million, so that if we bleed a sheep with a count of 15 million and the next day the count has fallen to 10 million, then although the new figure is well within the normal range, it is outside the M.A.D. for daily variation, and it is reasonable to assume that the fall is unlikely to be due only to experimental error and daily variation. This may appear to some people to be an abuse of mathematics but—bearing in mind that no biological test is 100% perfect —I have found it a useful and reasonably reliable standard.

The figures for the herbivorous farm animals are shown in the table with the figures for each constituent given as the mean and the standard deviation.

AVERAGES AND STANDARD DEVIATIONS

Leucocytes

Species	Total 10^3 p.c.mm	Differential count			
		Neutros.	Lymphos.	Monos.	Eosinos.
Horse	9·0 ± 1·6	58 ± 12	29 ± 11	5 ± 2·5	7 ± 3·5
Ox	8·0 ± 2·0	30 ± 10	52 ± 15	7 ± 4·0	10 ± 7·0
Sheep	9·2 ± 3·1	24 ± 9	68 ± 10	3 ± 2·7	4 ± 4·5

Erythrocytes

Species	Count 10^6 p.c.mm.	Hb. g./100 ml.	Corp. Vol. %	M.C.V. c. micra	M.C.H.C. %
Horse	7·0 ± 0·7	10·0 ± 1·5	28 ± 3·5	40 ± 4	35·5 ± 3·0
Ox	6·0 ± 1·3	11·8 ± 1·3	28 ± 3·5	49 ± 6	33·1 ± 3·5
Sheep	11·5 ± 1·8	12·4 ± 1·4	29 ± 4·0	27 ± 4	41·1 ± 4·0

In the table the sheep has an average of 11·5 million per c.mm. erythrocytes, roughly twice the human figure. The corpuscular volume is only 29%, giving us a total cell size of 27μ^3, about one-third the size of the human corpuscle. Although the other herbivorous animals have somewhat lower red counts, the corpuscular volume and the hæmoglobin concentration is about the same for all three.

In addition to the points shown by the table, there are other interesting differences. For example, the sedimentation rate in the horse is much faster, with a fall of about 4 cm. in fifteen minutes, than in ruminants where the fall may be almost unobservable even after twenty-four hours. This quick sedimentation in the horse is combined with a tendency for the corpuscles to form rouleaux and if a direct method of hæmoglobin estimation is employed, such as the Dare method, the formation of rouleaux may produce a field of scattered red specks. Hæmoglobin is also difficult to estimate by the ordinary Sahli method for at the dilution given by this method, the horse's hæmatin is too blue a brown to match the human standard. Cow's blood is also difficult to estimate by a direct method using a human standard, for it is too yellow. This yellow tinge may be due to the yellow colour of the plasma which cannot be estimated by standards employed for the human icteric index.

Besides the differences in erythrocyte size and numbers, there is a difference between the animals in erythrocyte regeneration. Wirth (1938) investigated this by bleeding animals until the red count was reduced to half and then examining the blood for regenerative changes. He found no reticulocytes in the horse and other regenerative changes were scarce. On the other hand, in the sheep reticulocytes were numerous with large numbers of polychromatic cells and many cells showing punctate basophilia. Thus both these herbivorous animals form a contrast to the dog and cat, where Jolly's bodies and nucleated red cells are the predominant change.

Neser (1923) has shown that the horse has another characteristic, for if it is excited the red count may show an increase of 1 or 2 million within a few seconds, and this suggests an easy way of rectifying a slight oligocythæmia.

The average leucocyte counts for herbivorous animals are all about 8,000 per c.mm. in contrast to other domestic animals, particularly the cat with an average of over twice this number. Figures for neutrophil percentage show that the horse is similar to man, having roughly double the number of neutrophil cells to lymphocytes, while in the ruminants this ratio is often reversed.

Cell types are similar to those in man. In carrying out differential counts the difficulty with ruminants lies in distinguishing between monocytes and large lymphocytes, in contrast to the horse where the difficulty during a neutrophilic reaction is to distinguish between monocytes and metamyelocytes. The most striking blood cell among all the domesticated animals is undoubtedly the eosinophil of the horse. If this cell is stained by Leishman, instead of seeing chunks of material stained eosin red, one sees a cell containing large orange globules giving it a most spectacular appearance. No one has attempted to explain the difference between this cell and the more common type of eosinophil but anyone attempting to work on a histochemical analysis of eosinophils would do well to include that of the horse.

Finally, there is one important difference between human blood and the blood of domestic animals, of great clinical importance. Hæmatology textbooks appear to avoid a direct statement on the matter, but in man there does not seem to be any line of demarcation between band forms and what can be called under the Cooke and Ponder count, a "Poly. I". In several of the domestic animals, "Poly. I's", resembling Schilling's "degenerative band forms" or Osgood and Ashworth's (1937) cells 78 and 79, are common and variable, on one day representing the majority of neutrophil cells and on another a small minority. If one includes these cells as band forms when carrying out a Schilling Index or some similar index, all sensitivity is lost, therefore in farm animals it is very necessary to ensure that one restricts the band forms to very definite metamyelocytes with a simple bandlike nucleus.

The Serum Proteins of the Domestic Animals

By John B. Brooksby, M.R.C.V.S.

My own experimental work on the normal serum proteins of the domestic animals is limited to studies on the ox and pig, and to complete the picture I have to rely on observations taken from the literature. I should, however, like to draw attention to several factors which obscure the comparative aspects of this subject.

The first of these is that the greater part of the data available in the literature is the by-product of other research. Observations have frequently been limited to those essential for the particular work in hand, and have not been extended to yield complete information on the normal. The second factor which complicates the comparative study is a technical one. With the development of protein chemistry new methods of characterization of the serum proteins have been discovered. The multiplicity of "salting-out" methods, and the variations resulting from what may seem minor changes in technique, have been considered in many of the earlier papers, notably in the review by Howe (1925). It appears likely that the existence of several different estimates for the protein fractions in any particular species is, in part, due to technical points such as those raised in the papers referred to. This situation does not render easier the comparison of species with species.

Just as in salt-fractionation, small differences in technique make for wide discrepancies in the results obtained by the methods of electrophoresis and ultracentrifugation. In electrophoresis, the pH, the buffer used, and the ionic strength of the medium greatly influence the apparent constitution of the serum. In ultracentrifugation, the dilution of serum used is an important factor and specification of the conditions of experiment is therefore essential to the presentation of results.

No comparison is yet available for salt and electrophoretic analyses made side by side on the same series of animal sera. Such comparisons do exist for human sera, and it is interesting that the proportion of protein assigned to albumin is generally higher for the salting-out method than for the electrophoretic. Figures for the relationship are given by Taylor and Keys (1943) for eight normal sera. The mean percentage of albumin in these sera was 71·4 by the salt method, while electrophoretic analysis gave a value of 65·9. The discrepancy appears to be even greater for pathological sera. Until similar figures are available for the sera of the domestic animals, we can compare only the normals established by different workers using the different methods.

The third factor which makes data for comparison difficult to obtain from the literature is that, in comparing the results of different authors, we are particularly at the mercy of variations in the animals studied, in respect of breed, age, sex, condition and so forth. Little is known of the effects of these factors in the sera under consideration, except in the outstanding case of the deficiency of the sera of the young ruminants in the orthodox globulin fractions. Less striking differences in the animals studied may add to the confusion between authors.

The values so far reported for bovine serum albumin expressed as a percentage of the total serum protein illustrate well the variations from author to author. They are 48% (Howe), 44% (Hartley), 47% (French), 54% (Brooksby), and 55% (Hewitt). These values were obtained by the "salting-out" method, using ammonium sulphate, sodium sulphate, or sodium sulphite. The value given by Svensson (1946) based on the electrophoretic analysis of ten sera is 41%.

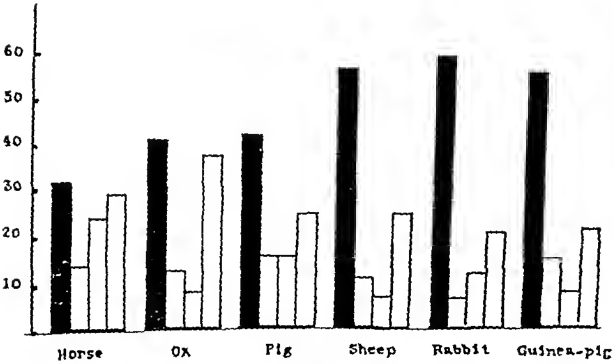

FIG. 1.—Percentage of total serum protein in electrophoretic fractions (for details see text).

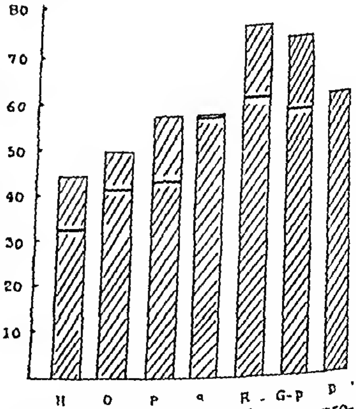

FIG. 2.—Percentage of total serum protein accounted for by albumin in various species. ("Salting-out" data.)

As the only data collected by one worker on the sera of several domesticated animals are those of Svensson referred to above, the above diagram (fig. 1), which I have prepared from the results given in the monograph, probably represents the best information on the differences which exist between the species concerned.

For each species, the first (shaded) column represents the albumin, and the others respectively the α β and γ globulins, each as a percentage of total serum protein. Comment on the wide differences between species does not seem necessary.

I have been unable to find a similar research by one observer on the "salting-out" of the fractions from the sera of different species. This seems an unfortunate gap in our knowledge, for, as is plain from the list of values for bovine serum albumin shown earlier, the observations of different workers on the same species may vary by as much as the species do among themselves. The next diagram (fig. 2), therefore, is a composite one, which I have prepared from the results of all the "salting-out" experiments on the sera of the species concerned, which I have encountered in the literature. The columns represent the percentage of the total serum protein accounted for by albumin in the sera of, respectively, horse, ox, pig, sheep, rabbit, guinea-pig, and dog. The line drawn across each of the first six columns shows the percentage of albumin estimated by the electrophoretic method, and this figure is taken from Svensson's results. The general trend of the "salting-out" results is thus the same as the electrophoretic, the greatest discrepancy is in the ovine serum, where, instead of the value by electrophoresis being 5 to 10% lower than the "salting-out" value, the two correspond closely. Otherwise, the results suggest that the relationship demonstrated for human serum also holds for animal sera.

I have not included the salt-fractionation of the globulins in this table, as even greater variations occur from author to author. My own estimate of the euglobulin for the cattle I have studied, based on precipitation with 15% sodium sulphite, is that it constitutes 10% of the total serum protein. Howe's figure is 12%. In the pig, the euglobulin fraction appears larger: the value I have found is 18%.

Of the implications of these species differences in the serum proteins for the economy of the animal it is difficult to say much. The effect on the osmotic pressure exerted by the serum of changes in the albumin-globulin ratio has been studied by several workers. Human serum was compared with horse serum by Marrack and Hewitt (1927), and the osmotic activity per gramme of protein found to vary as expected with the albumin-globulin ratio.

From the immunological point of view, the size of the globulin fraction in equine and bovine sera is sometimes a disadvantage. If a particular antibody occurs in some concentration in all the globulin fractions, "purification" of antibody by separation of a small part of the serum protein, carrying the entire activity of the serum, is obviously impossible by the conventional technique. Of course, the existence of a large globulin fraction does not preclude the possibility of the isolation of the activity in a sub-fraction such as the well-known Felton fraction in anti-pneumococcal horse serum.

These considerations apply equally well to the electrophoretic fractions. In my own experiments with the antibody to foot-and-mouth disease, in bovine serum, the antibody appeared to be associated with the γ globulin. On Svensson's estimate of 38% of the total protein for the concentration of this fraction, separation of the entire γ globulin would give only very poor concentration of antibody. This is a very different picture from the concentration of antibodies in human serum by Cohn and his co-workers, when isolation of the γ globulin gave a tenfold concentration of antibody activity.

The Constituents of Normal Human Blood

By C. L. OAKLEY, M.D.

THE first speaker has made it abundantly clear that the domestic animals so far examined show a remarkable variability in their blood picture. Counts of red or white cells show a variability from animal to animal seldom less than 10%, often far greater; determinations of mean corpuscular volume or mean corpuscular hæmoglobin content are equally variable. Man, by comparison, shows very little variation, and I had hitherto supposed that this was due to his large size and low metabolic rate with its consequent long cell survival time. I still think that there is a good deal of truth in this though it is very difficult on this basis to explain away the high variability of the horse. [A chart of determinations of the constituents of normal human blood was shown.]

Red cell counts and hæmoglobin determinations in man have a variability of 5 to 6% and the frequency distribution of the values obtained is a close approximation to a "normal" curve. The "orthochromic" cells form about 98% of the population, and the percentage of immature cells (reticulocytes) seldom exceeds 2%. In other words the slow replacement rate is associated with a low variability in numbers. There is a high correlation between number of red cells and hæmoglobin percentage, so that the mean corpuscular hæmoglobin concentration is fairly constant. Similarly, low variability is found in the mean corpuscular diameter (2·4%), mean corpuscular hæmoglobin (3·6%), and mean corpuscular hæmoglobin concentration (3·3%).

Two striking differences in hæmoglobin concentration may be noted. Women on the average have lower hæmoglobin concentrations than men; possibly this may be in part due to dietetic factors. Americans, on the average, have higher hæmoglobin concentrations than Britons; a fact that Price-Jones attempted to explain by supposing that Americans, who spend a high proportion of their time in motor-cars, suffer from mild chronic carbon monoxide poisoning, with consequent plethora.

It is worth noting that most domestic animals have red cell counts per c.mm. greater than that of man, while their packed cell volume is much lower; the red cell volume is therefore less than that of man. It would be interesting to consider the advantages of the small red cell in large numbers as compared with the large red cell in small numbers; questions of viscosity and rapid turnover of oxygen readily come to mind.

The counts for white cells in man have a frequency distribution differing greatly from the "normal" curve and a much higher variability than the determinations previously referred to. Indeed, it is rather doubtful whether the use of the normal curve is justifiable in dealing with the frequency distribution of a population so heterogeneous as that of white cells. White cells are short-lived and are rapidly replaced; a high variability in the white count would therefore be expected, though this might be somewhat reduced if the distributions of the individual cell types were considered separately. Like the horse, man has a high neutrophil and low lymphocyte count; in most domestic animals the proportion is reversed. True neutrophils occur, as far as I know, only in anthropoid apes and man; most so-called "polymorphs" in other animals differ greatly from human neutrophils.

Salting-out and electrophoretic methods separate the proteins in human plasma into several groups; the ones generally accepted are albumin and globulin (including fibrinogen). Electrophoretic examination divides the globulin fraction into five fractions, amounting altogether to about 40% of the total plasma protein; the remaining protein (60%) is albumin, giving an albumin-globulin ratio of 1·5. This figure is much higher than that of most domestic animals; salting-out methods give an even higher ratio.

Inherited Disorders of the Blood in Rodents

By HANS GRÜNEBERG, M.D.

THIS short paper deals only with the more important inherited blood disorders known in rodents and their main features.

Macrocytic anæmias in the mouse [1, 6, 9].—Two semi-dominant genes, W and W^{v}, are known which cause variegated spotting in the heterozygous condition ($W/+$ and $W^{v}/+$) and white fur with black eyes in the homozygotes W/W and W^{v}/W^{v} and in the compound W/W^{v}. W/W mice have a severe orthochromic macrocytic anæmia which proves fatal within a few days after birth; W/W^{v} is similarly but less severely affected and survives often until weaning age and occasionally beyond; W^{v}/W^{v} is more mildly affected, but adults are nearly always sterile; $W^{v}/+$ is mildly macrocytic; but not clinically anæmic, while $W/+$ is completely normal hæmatologically. The anæmia of W^{v}/W^{v} mice is refractory to liver treatment [6]. W/W mice can be kept alive by repeated intraperitoneal blood injections [5], but it is not certain whether this is due simply to a transfusion effect or to the presence in the normal blood of a chemical compound lacking in the anæmic mice. W^{v}/W^{v} anæmics can be acclimatized to very low atmospheric pressures like normal mice, and they show normal powers of recuperation from a superimposed secondary anæmia [6].

Siderocyte anæmia in the mouse [12, 7, 8].—The recessive gene for flexed tail and belly spot is associated with a normocytic hypochromic anæmia which develops on the 13th day of pregnancy and disappears again spontaneously during the first month after birth. The clinical anæmia is thus confined to the period of liver hæmopoiesis, while cells produced in the yolk sac or bone-marrow are normal or very nearly so. The hypochromic cells contain granules of free (non-Hb) iron. Such "siderocytes" [8] in small numbers are a normal feature of mammalian blood [2, 3]. They appear to be ageing cells about to be withdrawn from the circulation and hence are the counterpart of the juvenile cells or reticulocytes. Siderocytes are increased in numbers in all human hæmolytic conditions examined [4, 2] and their percentage affords a measure of the severity of the hæmolytic process. In practice they can be used as a very sensitive indicator for chronic lead poisoning.

Splenomegalic anæmia in the mouse [11].—A recessive condition arising before birth whose hæmatology has not yet been worked out in detail.

Acholuric jaundice in the rat [10].—The clinical condition is completely recessive, but many heterozygotes have reduced resistance of the erythrocytes to hypotonic saline and a reticulocytosis without jaundice. Homozygotes are heavily jaundiced at birth or soon after, but survive and are fertile. Microcytosis, reticulocytosis and increased fragility are associated with splenomegaly, but splenectomy does not cure the condition.

Lethal spherocytic anæmia in the rat [15].—A recessive condition which develops rapidly a few days after birth and proves fatal within a fortnight or so. The red cells are spherocytes; reticulocytes are greatly reduced in numbers, while the white count is considerably increased (mostly neutrophils). Some jaundice is present, and there are considerable hæmosiderin deposits in the liver and, to a lesser extent, under the splenic capsule. The hæmopoietic tissue in the bone-marrow is reduced. From the latter fact and the time of onset of the anæmia, it seems that the medullary hæmopoiesis is mainly (? wholly) at fault, and that its products are of an inferior quality with a reduced survival time in the circulation.

Erythroblastosis fœtalis in the rabbit [14].—No details have been published yet, but according to a personal communication it appears that the clinical picture as well as the mechanism of this disease is analogous to the human condition, depending on an antigenic incompatibility between mother and fœtus.

Pelger anomaly in the rabbit [16, 13].—A semi-dominant condition very like that described in man. In heterozygotes, which are fully viable, the nuclei of the polymorphs are either entirely unsegmented (sausage and horseshoe shapes) or consist of two segments only; normally segmented forms are rare. While the homozygous form in man is so far unknown, it has been produced in the rabbit. The nuclei of its "polymorphs" are entirely spherical. The homozygote is inviable and seems to have skeletal abnormalities in addition to its abnormal blood picture.

It will be obvious that a more detailed study of these inherited blood disorders will be of considerable interest for medical research. With the exception of the two rat genes, all the conditions mentioned above are accessible in this country.

Professor G. R. Cameron showed a chart giving data on the blood picture, blood volume and plasma proteins of normal goats. He drew attention to the high normal level of red cell counts and hæmoglobins, pointing out that this was associated with an active red bone-marrow and small red cells in the blood. He commented on the strange reversal of albumin-globulin ratio in the plasma.

Dr. R. E. Rewell: It is surprising how little work has been done on the blood constituents of animals other than those used in laboratories or as farm animals in temperate regions.

From a hæmatological point of view, even so long-domesticated a species as the camel has been dealt with in a very superficial manner, and the best comparative study that I know is that on size and shape of the erythrocytes in several species by Gulliver in the *Proceedings of the Zoological Society of London*, as long ago as 1875. This paper even included observations on whales.

I am glad that it has been emphasized that there are marked differences between cells which are assumed to be homologous in different species. Thus in the vicuna, which I have studied recently, cells which one can only call polymorphonuclear neutrophils have granules which are finer and more acidophilic in my preparations than those of man and the average number of lobes in the nucleus is as many as fifteen. In the same animal the cells which I can only assume to be monocytes appear in first preparations to have stellate nuclei, but these are not good preparations and I have not been able yet to apply methods of supravital staining. In the few animals of this group and a few rodents which I have studied, all had smaller red cells than man.

On the biochemical side, observations appear to be even more meagre. However, Turner in America has made observations on the colloid osmotic pressure of the blood and the blood proteins in the bonito, toadfish and sea bass. In the latter animal it is of interest to note that the level could be raised by an abundant diet. Studies have, of course, been made on the blood of animals with aglomerular and atubular kidneys in connection with the elucidation of renal function.

DISCUSSION ON THROMBOSIS

Mr. H. J. B. Atkins: *Post-operative thrombosis.*—A limited degree of venous thrombosis is a natural response to operative trauma, but sometimes thrombosis appears at a distance from the site of the operation often in the veins of the leg. Is this a true "remote thrombosis" or is it in reality an extension from the site of the operation? Four arguments may be cited:

(1) "Thrombosis in continuity" does occur as, for instance, jugular vein thrombosis after mastoid operations and axillary vein thrombosis after radical mastectomy. However, between 1920 and 1925 at Guy's Hospital there were two cases of thrombosis of the axillary vein, one after gastrectomy and the other after prostatectomy; while of the two cases of thrombosis following radical mastectomy, both occurred in the left femoral vein.

(2) It is a fact that thrombosis of leg veins is far more common following operations in which the abdomen has been opened and it is suggested that this may be a direct spread through the inferior epigastric veins: but in the Guy's series quoted above seven cases of thrombosis followed appendicectomy by a gridiron incision, and all of these were in the left leg. If this had been a spread from the operation field, the right leg would be expected to have been the more common site. Furthermore, the increased incidence after laparotomy can be explained on the grounds that the diminished respiratory excursions consequent upon such an operation have a pronounced effect in slowing the venous return from the legs and so predispose to thrombosis.

(3) Operations upon the pelvic organs, particularly prostatectomy, have a bad reputation for leading to thrombosis of the leg veins, and it has been assumed that this is due to a direct spread from the peri-prostatic and other pelvic plexuses. Reference to the Guy's series shows that this supposedly high incidence following pelvic operations is not noticeable when the age factor is considered. Many pelvic operations, particularly prostatectomy, are performed on middle-aged and elderly patients who are naturally more prone to venous thrombosis and in fact the incidence (10 : 1,000) of thrombotic complications is as high after operations upon the stomach, duodenum and gall-bladder as upon the uterus.

(4) In a case of my own, amputation of the right leg was followed by thrombosis in the left leg without any sign of thrombosis in the stump, and in another case, the insertion of a *Kirschner* wire through the lower end of the right femur was followed by thrombosis of the left femoral vein.

well as the mechanism of this disease is analogous to the human condition, depending on an antigenic incompatibility between mother and fœtus.

Pelger anomaly in the rabbit [16, 13].—A semi-dominant condition very like that described in man. In heterozygotes, which are fully viable, the nuclei of the polymorphs are either entirely unsegmented (sausage and horseshoe shapes) or consist of two segments only; normally segmented forms are rare. While the homozygous form in man is so far unknown, it has been produced in the rabbit. The nuclei of its "polymorphs" are entirely spherical. The homozygote is inviable and seems to have skeletal abnormalities in addition to its abnormal blood picture.

It will be obvious that a more detailed study of these inherited blood disorders will be of considerable interest for medical research. With the exception of the two rat genes, all the conditions mentioned above are accessible in this country.

Studies have, of course, been made on the blood of animals with aglomerular and atubular kidneys in connection with the elucidation of renal function.

only the freshly formed thrombus which is liable to become detached. What we as clinicians would like to ask the pathologists is "How fresh?" In heparin and dicoumarin we have substances which will protect our patients from thrombus formation, but the former is troublesome and the latter occasionally dangerous to use, so that we wish to cut down the period of their exhibition to a minimum, and to rely as soon as we can on the natural protective mechanism of ambulation, though of course this protection is not absolute. If we knew more about the pathology of detachment we could say "after such and such a time there is no longer danger of this clot becoming detached, we may now discontinue anti-coagulant therapy and allow our patient to get up". At present we use an empirical period of two or three weeks, during which we apply our anti-coagulant therapy. This period is probably unnecessarily long and our patients are therefore subjected to unnecessary inconvenience, danger and delay. That the danger is a real one is exemplified by two cases upon whom gastrojejunostomy had been performed and who developed post-operative venous thrombosis in the leg veins. Both cases were treated by dicoumarin in comparatively small doses, both were adequately controlled by daily estimations of prothrombin time, and yet both developed severe hæmorrhages presumably from the suture line and both were only just saved by the timely administration of blood transfusions and vitamin K.

I would, therefore, conclude with the plea that, concurrently with the magnificent work that pathologists are doing in clearing up our ideas of clot formation, they should turn their attention to elucidating the problem of the pathology of detachment. In this way they will amplify and complete the great help that they are affording to the clinician in his treatment of this common and dangerous complaint.

Dr. R. H. D. Short: *Pathology of primary or idiopathic thrombosis of the leg veins.*—The causes of thrombosis are referred to changes in four fields:

Changes: (1) in the plasma; (2) in the corpuscular elements of the blood, particularly the platelets; (3) in blood flow; and (4) in the vessel walls.

A post-mortem examination of a case that has died from pulmonary embolism will illustrate their results.

The history of the patient may record an operation a week or ten days earlier from which a good recovery was made, though perhaps associated with slight pyrexia and slight pains in the calf muscles. This may have cleared up satisfactorily only to be followed by the final catastrophe. Opening the pulmonary artery, we discover the cause of death. It is a long coiled thrombus completely blocking both main branches of the pulmonary artery. Removing the thrombus and carefully disentangling its coils we find it measures about 55 cm. It may be branched particularly near one or other extremity, and towards its narrower end its colour may be much less red than is the larger portion. The paler portion is firm, almost completely inelastic and may show obvious signs of having been broken off, in contrast to the thicker end of the thrombus which is rounded. We suspect at once that the thrombus was formed in one or other femoral vein, and opening both of them we find an empty left femoral vein and the right occupied with a long thrombus. The embolism must therefore have occurred from the left femoral vein which we found empty. We also see that had the clot from the left vein been removed surgically, a second was lurking in the right femoral vein.

Let us now replace the thrombus in the position it occupied before the embolism occurred. The broken, pale end, the "kopfteil" as Aschoff would call it, fits on to the broken end projecting from the left popliteal vein. The branches near the lower

These arguments lend support to the theory that leg vein thrombosis after operation is a "remote thrombosis" and has a distinct and pathological ætiology differing from that of the physiological and insignificant "thrombosis in continuity".

Lately Gunnar Bauer (1946, *Lancet* (i), 447) has confirmed these findings by observing the early stages of clot formation in a phlebogram. He places the origin of post-operative venous thromboses in the small veins of the calf muscles whence they extend into the large venous trunks of the limb, and either obstruct the venous return and give rise to œdema, or are detached and lodge in the pulmonary arterial tree as emboli. Apart from the grave consequences of detachment, Bauer points out how a very high proportion of these cases develop late manifestations such as chronic œdema and leg ulceration if the thrombosis is allowed to develop beyond the initial stages where it must be arrested therapeutically if such tragic consequences are to be avoided. The earliest stages of thrombosis can be detected clinically by finding spots of tenderness deep in the calf muscles when the knee is flexed and the foot planted on the ground to relax these muscles; or by eliciting pain in the calf (not present on the other side) when, with the straightened knee, the ankle is forcibly dorsiflexed. Such signs call for immediate anti-coagulant therapy.

If we accept the theory of remote thrombosis the pathology of clot formation can be expressed as follows:

Intrinsic factors
(age, &c.)
+
Operation
(increased platelets and fibrinogen, recumbency, sluggish circulation)
+
? sepsis
} Tendency to thrombosis
+
Anatomical factors
(Obstruction of femoral veins especially left by loaded colon and the crossing of the left common iliac vein by the right common iliac artery)
} Thrombosis of the leg veins, especially on the left side

So much for the pathology of clot formation; what of the pathology of clot detachment? First let us consider the effect of sepsis. Whatever part sepsis may play in the formation of the clot by causing an endophlebitis, it certainly influences the possibility of clot detachment and determines what type of detachment—large or small—may take place. As a result of an analysis of the Guy's series, I envisage the effect of sepsis to be represented by the following scheme:

Thrombosis of leg veins	+	Absence of infection	=	danger of massive pulmonary embolus
	+	Mild infection	=	Anchoring of clot to vein wall by endophlebitis with œdema and pain. Portions may become detached by septic softening of the clot and lead to small infarcts
	+	Severe infection	=	Multiple septic infarcts

The use of the anti-coagulants heparin and dicoumarin has diminished the incidence of embolic manifestations following thrombosis. Now, in all probability, these substances can only act by preventing the formation of fresh thrombus and, if they have a protective effect in regard to embolus formation, it argues that it is further work showed that exactly similar hæmorrhages were found in the wall of the pulmonary artery after embolism. Here, the infarction must be the result of embolism. It cannot be due to blocking of the venous return of the vasa which empties into the bronchial veins in the case of the pulmonary artery. Vasal openings into the lumen of large veins or arteries are not, in my experience, normal and are the result either of old organized thrombosis or of arterio- or phlebo-sclerosis. These medial infarctions seem therefore to be the result of thrombosis rather than its cause.

Adherence of a formed thrombus will be favoured by all factors which stop blood flow and thus allow the vein wall to rest against the thrombus and so to increase the surface over which organization can occur. Organization proceeds rapidly and prolonged rest would seem to be unnecessary and may indeed provoke further thrombosis in what would otherwise have been healthy veins. Venous trabeculæ such as occur at the origin of the common iliac vein will act as a natural barrier to embolism.

Embolism, on the other hand, will be favoured by factors which increase blood flow and therefore increase friction on the surface of the thrombus. Increase of friction may be one factor in determining the remarkably constant length at which fracture of the thrombus occurs. Increased friability or even liquefaction of the thrombus may well be another important factor. In one case both femoral veins had originally contained thrombi extending from the inguinal ligament to below the knee. At autopsy only the upper and lower ends of the thrombi were in situ; the intervening sections had completely liquefied over a length of about one foot in both veins.

Aschoff came to the conclusion that the cause of spontaneous thrombosis lay in the blood—in its chemistry or in its hydrodynamics. In the present state of knowledge we cannot advance beyond this point though we can repeat the central problem of thrombosis which is to answer the question "why platelets deposit where they do".

Dr. Helen Wright: *Blood findings.*—The history of blood platelets goes back for nearly a century. Schultze in 1865 noticed that small granules were present in shed blood from which thin fibrils radiated during the process of coagulation. But it was not until nearly twenty years later, when the importance of these elements in thrombosis was recognized by Bizzozero (1882) and also by Eberth and Schimmelbusch (1886), that the modern experimental approach to the study of platelets can be said to have started. These workers were the first to observe that when a blood-vessel wall is damaged, a thrombus, formed of adherent platelets and white cells, becomes deposited at the site of injury to which it tends to adhere. Since then these observations have been frequently confirmed both in the human subject and in experimental animals. In this connexion the work of Rowntree and Shionoya (1927) in the United States, and of Best and his colleagues (1938) in Toronto may be mentioned.

The work of Hueck in 1926 on the part played by platelets in thrombosis was confirmed and amplified the following year by Dawbarn, Earlam and Evans (1928). All these observers found that a very marked increase in the numbers of circulating platelets followed surgical operations and parturition. This rise in count is apparent by the fifth or sixth day after operation or delivery, reaches a maximum about the tenth day and subsides to its original level again between the fourteenth and twenty-first days. The degree of the rise in numbers is correlated with the extent of tissue damage, a small superficial operation being followed by a slight rise in the platelet count, while a major operation, and especially one involving abdominal interference, end have come from the muscular veins and one large branch near the upper end evidently fits into the proximal part of the profunda femoris vein.

It is thus established that the pale end lay distally in its original position, and subsequent microscopical examination shows the typical laminated structure characteristic of the oldest part of the clot. The red portion, in many cases forming much the larger part of the thrombus, shows much less structure. Though both parts may show ripple lines of Zahn to the naked eye, these are no criteria of the age of a thrombus, which can only be settled by histological examination and by observing the platelet scaffold, which is much reduced or almost absent in the red portion. The white clot containing the platelet scaffold was therefore interpreted by Aschoff as being formed in circulating blood in contrast to the red portion, formed by massive thrombosis in a stagnant column of blood. We thus know that the oldest part of the clot lay near the knee, and the most recently formed portion lay nearest the inguinal region. The length of the clot—Aschoff says the majority are between 45 and 55 cm.—thus corresponds to the variation in the length of the femoral vein between the male and the female.

This autopsy has drawn attention to several important facts. In the first place, the clot has formed below the knee. If the distal tibial veins are opened we shall find still older, adherent, perhaps even organizing clot which can be traced into the muscular veins of the calf and even into the plantar veins. If routine examination is made of the calf veins of all cases brought to autopsy, thrombosis of these muscular tributaries is found in 22% of cases—a surprisingly high incidence. The condition may account for the transient pyrexia and calf pains noticed in the clinical history of the patient. Several surgeons, Homans in America and Bauer in Scandinavia, have drawn attention to this complication. Moreover, there are certain peculiarities about the distribution. It is found most commonly in the muscular veins to the soleus and posterior tibial muscles. The superficial, gastrocnemius muscle is usually much less affected and often escapes completely. The veins to the soleus may be widely distended with clot almost resembling varicose veins. In such cases the posterior tibial or popliteal veins may be empty and the factors which decide whether the thrombosis will spread to the larger vessels are unknown.

Routine dissection also shows that the site of thrombosis may be multiple—widely distant muscular thrombi being found with no intervening thrombosis. Or thrombosis may occur in adjacent valve sinuses with no intervening clot.

Though primary venous thrombosis is found to be so common in muscular veins of the calf and foot, it is interesting to find that there are no correspondingly common sites of thrombosis in the arms or back. Why this should be so is unknown—we may speculate upon hydrostatic factors depending on the arrangement of veins in the lower leg. Homans claims to have demonstrated histological evidence of muscular degeneration in the calf muscles which may be associated with the thrombosis. There is no proof that it is the cause. These facts are of importance in focusing attention on the primary site of thrombosis where the earliest clinical evidence may be corroborated by radiography of the veins as described by Bauer. A successful technique will demonstrate filling defects in the tibial veins and may even show the eel-like stage of thrombosis which immediately precedes a fatal embolism. In such a case, radiography may be the only clue to impending catastrophe—clinically, the stage may not be recognized.

Histological examination of the vein wall often shows an appearance of infarction of the media at the site of primary thrombosis. This observation suggests that thrombosis might be the result of interference with nutrition of the vein wall as a result of changes in the vasa vasorum. Though the idea was superficially attractive, further work showed that exactly similar hæmorrhages were found in the wall of the pulmonary artery after embolism. Here, the infarction must be the result of embolism. It cannot be due to blocking of the venous return of the vasa which empties into the bronchial veins in the case of the pulmonary artery. Vasal openings into the lumen of large veins or arteries are not, in my experience, normal and are the result either of old organized thrombosis or of arterio- or phlebo-sclerosis. These medial infarctions seem therefore to be the result of thrombosis rather than its cause.

Adherence of a formed thrombus will be favoured by all factors which stop blood flow and thus allow the vein wall to rest against the thrombus and so to increase the surface over which organization can occur. Organization proceeds rapidly and prolonged rest would seem to be unnecessary and may indeed provoke further thrombosis in what would otherwise have been healthy veins. Venous trabeculæ such as occur at the origin of the common iliac vein will act as a natural barrier to embolism.

Embolism, on the other hand, will be favoured by factors which increase blood flow and therefore increase friction on the surface of the thrombus. Increase of friction may be one factor in determining the remarkably constant length at which fracture of the thrombus occurs. Increased friability or even liquefaction of the thrombus may well be another important factor. In one case both femoral veins had originally contained thrombi extending from the inguinal ligament to below the knee. At autopsy only the upper and lower ends of the thrombi were in situ; the intervening sections had completely liquefied over a length of about one foot in both veins.

Aschoff came to the conclusion that the cause of spontaneous thrombosis lay in the blood—in its chemistry or in its hydrodynamics. In the present state of knowledge we cannot advance beyond this point though we can repeat the central problem of thrombosis which is to answer the question "why platelets deposit where they do".

Dr. Helen Wright: *Blood findings.*—The history of blood platelets goes back for nearly a century. Schultze in 1865 noticed that small granules were present in shed blood from which thin fibrils radiated during the process of coagulation. But it was not until nearly twenty years later, when the importance of these elements in thrombosis was recognized by Bizzozero (1882) and also by Eberth and Schimmelbusch (1886), that the modern experimental approach to the study of platelets can be said to have started. These workers were the first to observe that when a blood-vessel wall is damaged, a thrombus, formed of adherent platelets and white cells, becomes deposited at the site of injury to which it tends to adhere. Since then these observations have been frequently confirmed both in the human subject and in experimental animals. In this connexion the work of Rowntree and Shionoya (1927) in the United States, and of Best and his colleagues (1938) in Toronto may be mentioned.

The work of Hueck in 1926 on the part played by platelets in thrombosis was confirmed and amplified the following year by Dawbarn, Earlam and Evans (1928). All these observers found that a very marked increase in the numbers of circulating platelets followed surgical operations and parturition. This rise in count is apparent by the fifth or sixth day after operation or delivery, reaches a maximum about the tenth day and subsides to its original level again between the fourteenth and twenty-first days. The degree of the rise in numbers is correlated with the extent of tissue damage, a small superficial operation being followed by a slight rise in the platelet count, while a major operation, and especially one involving abdominal interference, elicits a rise of 100% or more. Recently I have been able to confirm these conclusions by performing graded operations in experimental animals (Wright, 1945). Other factors which affect the platelet count, such as diurnal changes, menstruation, infection and exposure to ultraviolet light are now well recognized. It has been suggested that the rise in numbers is a response to absorbed products of tissue autolysis which stimulate the megacaryocytes of the bone-marrow. The experimental injection of muscle-press juice and also of some proteins and products of protein digestion are followed by a rise in numbers though, so far as I know, no detailed chemical analysis of these materials has yet been made. Consequently no particular fraction can be incriminated as the stimulating substance for platelet formation.

But though the numbers of platelets rise after operations and their participation in the formation of white thrombi in injured vessels may be accepted as fully proven, the precipitating cause of thrombosis is still far from clear. It seemed to me, therefore, worth while to try to make quantitative observations upon the already recognized, but unmeasured property of platelets—their adhesiveness, since this characteristic seems to play so large a part in their conglutination. For this purpose, venous blood samples, treated with a minimum of heparin to ensure that no clotting took place during the course of the experiment, were introduced into special glass tubes which were carried on a large rotating wheel (Wright, 1941). The tubes containing blood were rotated at about four revolutions a minute so that it formed a thin moving layer over the surface of the glass. The tubes had windows in their sides which were closed by coverslips held in place by a thin smear of vaseline.

The windows were carefully ground so that the shoulder between the tube and the coverslip should be as small as possible, to prevent the formation of eddies at that point. The object of the window was to enable a representative section of the glass over which the blood passed during rotation to be examined microscopically at the end of the experiment. In this way the presence of adherent platelets was demonstrable in very large numbers and it may be assumed that comparatively few had disrupted during the eighty minutes of rotation. An initial platelet count was made on the sample, and I found that a direct wet method, using an ordinary red cell counting chamber and hæmocytometer pipette gave the most reliable and consistent results. Samples for counting were withdrawn every ten minutes from the rotating tubes and it was found that the count fell progressively so that, when plotted, the curves were of logarithmic type. The variation for normal bloods containing the same amounts of anti-coagulant fell within fairly narrow limits. By altering the amount of anti-coagulant, the slope of the curve can be altered. Three curves obtained from the same blood sample treated with 0·05, 0·2 and 0·8 mg. per c.c. blood respectively, demonstrated that the adhesiveness of the platelets is decreased with increasing concentrations of heparin. Even with the highest concentration of anti-coagulant, however, it is not possible to render the platelets completely non-adhesive and some continue to stick to the wall of the tube, an observation which is in agreement with the observations made *in vivo* by Shionoya and Best. Having determined the range of the stickiness of the platelets in normal subjects, I went on to make observations on patients during the post-operative period. The changes in this property were found to run parallel with the rise in their numbers. This correlation held good for surgical patients, women after delivery and in experimental animals after operations. Both the stickiness and the numbers were maximal at about the tenth day after operation or delivery.

The history of a healthy woman of 33, who underwent three spontaneous thrombotic crises following the repair of a small right femoral hernia serves to illustrate the association between thrombosis and platelet stickiness. She was under observation at the time and I was able to follow her platelet count and stickiness during the period in which they took place. Before operation both the numbers and the adhesiveness of her platelets were normal. On the seventh day after the operation, her left leg became painful and a thrombosis was diagnosed.

Her platelet count had by then increased from the pre-operative level of 240,000 to 580,000, and their stickiness was markedly increased. During the ensuing three weeks the condition subsided but at the end of this period she again complained of pain in the same leg and a further thrombosis was diagnosed. The platelet count on that day was 380,000, about the upper limit of normality, but the platelets were still unusually sticky.

Fourteen days later the platelet count had dropped to a level well below that found pre-operatively and the stickiness was returning towards normal. But that was not the end, for a week later and nine weeks after the repair of her hernia, she again developed a thrombosis. This time the platelet count was quite normal, 240,000, but an estimation of stickiness again revealed that they were abnormally adhesive. After this her convalescence was uninterrupted and she was discharged about three months after admission. In this case, therefore, all three crises appeared to coincide with phases of abnormal stickiness of the platelets.

I can offer no explanation as to why the platelets remained abnormally adhesive in this patient. Between the thromboses they returned towards normal, but never quite reached the pre-operative condition. It is also noteworthy that the count was normal at the time of the second and third thromboses, so that their initiation can hardly be ascribed to any increase in platelet numbers.

It is not yet known to what substance in their surface membrane the platelets owe their stickiness. It appears that this property is correlated with the age of the cell. Young platelets are more adhesive than are the older ones, a variation common to all young blood elements. Formerly I had inclined towards the suggestion made by Shionoya, that the platelet is covered by a thin film of fibrin, and on several theoretical grounds this explanation was satisfactory. It fitted in with their rate of migration in electrophoretic cells, with their behaviour with various types of anti-coagulant both *in vivo* and *in vitro* and with observations on their reduced stickiness in hæmophilia. Recently, however, my attention was drawn to a published case in which no trace of fibrinogen could be demonstrated in the plasma by the usual chemical tests, but in whose blood the platelets, normal in number, were reported to adhere together normally and to form white thrombi (Pinniger and Prunty, 1946). Whether it is necessary, therefore, to postulate some other mechanism than a surface fibrin film to account for the adhesive property of platelets, or whether the amount of fibrin required to render them adhesive is too small to be detected by methods used for estimating the concentration of fibrinogen in plasma, it is not yet possible to say.

Finally I should like to draw your attention to a further interesting functional change which commonly occurs in the post-operative state. It has long been suggested that circulatory stasis in the lower limbs plays a significant part in the initiation of thrombosis. Recently several workers have recorded observations made upon the rate of blood flow in the limbs after a few days' confinement to bed. Using a sodium cyanide injection method to study changes in the circulation rates after operations, Smith (1940) and her colleagues found that the time taken for blood to flow from the legs to the carotid sinus steadily increased for a number of days. Much less slowing was demonstrable in the arm to carotid sinus time during the same period so that it seems almost certain that the delay took place in the veins of the leg. How closely these changes in circulation time correspond with those in both platelet numbers and adhesiveness and how these together closely parallel the incidence of clinically diagnosed thrombosis, can be seen in fig. 1.

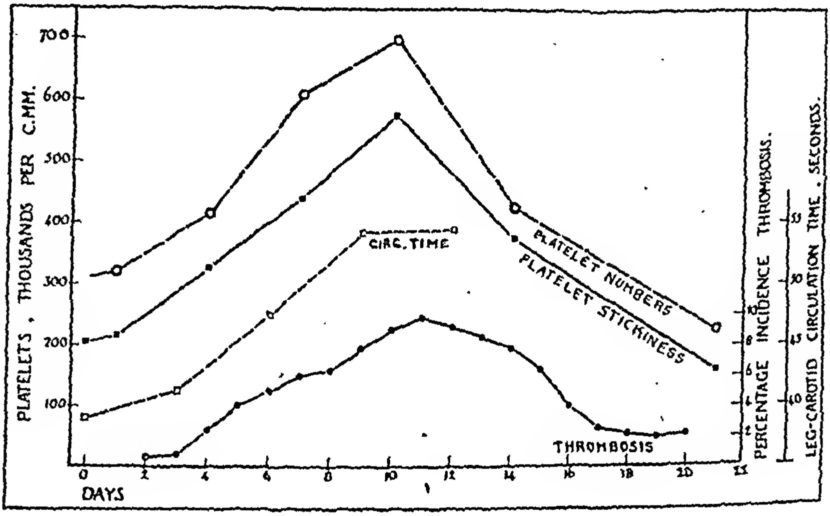

Fig. 1.

The peaks in all these curves fall suggestively near together in time and one is tempted to assume that they must be in some way causally connected and not merely coincidental. There may, of course, be some initiating or "trigger" factor capable of coming into action when other conditions in the blood are particularly favourable and whose participation in thrombosis has as yet escaped us. On the other hand all the main factors may now be known, and post-operative thrombosis takes place when all of them happen to develop high maximal values in any one patient on the same day.

Some Problems of Renal Lithiasis

PRESIDENT'S ADDRESS

By R. H. O. B. Robinson, F.R.C.S.

Many excellent papers on the subject of calculus in the upper urinary tract have been read before this Section. Lett (1936) described a thirty-year survey at the London Hospital which included 2,100 cases of renal and ureteric stone. He mentions the higher incidence in the male sex and the very high incidence of associated infection. In a group of 546 cases of stone in the upper urinary tract, sterile urine was found in only 12%.

Winsbury-White (1938) reported a series of cases also stressing the higher incidence in males and pointing out the preponderance of stone in the upper urinary tract as compared with the lower. He confirmed this (1946) in a further detailed statistical report.

I propose to discuss some particular problems bearing on the ætiology, diagnosis and treatment of stone in the upper urinary tract, drawing attention to several points which are still unsolved and some difficulties which I have encountered personally. The following is an illustrative case.

A young woman aged 22 in 1936 developed backache, considered to be due to spondylitis and for which treatment with heat and massage was initiated. Right-sided abdominal pain developed and two years later the appendix was removed without in any way influencing the symptoms. On interrogation she stated that all her life she had had frequency of micturition. In due course, in 1943, she was called up for service. In 1944 an attack of dysuria developed, but later in the year she proceeded to the Middle East, where a fresh attack of cystitis with hæmaturia occurred. Renal investigation, then carried out for the first time, showed bilateral renal calculi and a renal function of 48%. Retrograde pyelograms showed definite dilatation of the calices on both sides. Twelve months later the urine still contained pus but was sterile. The general condition was fair with a blood urea of 40 mg.%, but backache was persistent. X-rays at this stage showed a definite increase in the opacities, particularly in the right upper calix, and an operation was carried out to remove this upper fragment, which was discovered by preliminary needling of the kidney followed by splitting the upper pole. This was presumably done for the dilatation of the upper calix above the stone, although there was some increase in the dilatation of all the calices on both sides. Convalescence was uneventful and the post-operative X-rays showed the upper fragment removed but a definite increase in the remaining stones, while the intravenous pyelogram still showed gross dilatation particularly of the upper calix. One year later, that is to say eight years after the onset of the original symptoms, I was consulted to advise for relief of the persistent backache. The

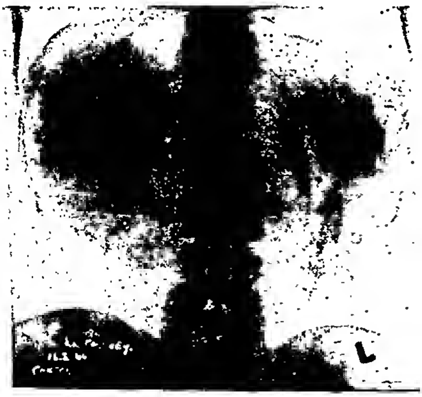

Fig. 1.—Multiple stones, both kidneys.

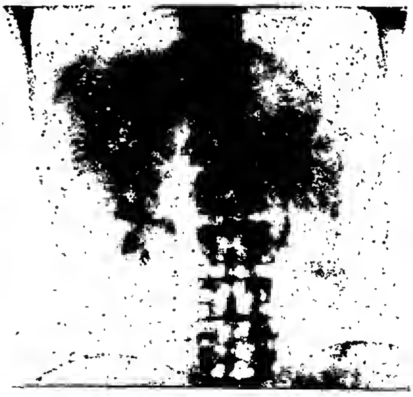

Fig. 2.—Associated dilatation of calices.

present position is that the pain is now more prominent on the left side and there is some nocturnal frequency. No obvious physical signs are present, but X-rays of the spine show bone changes of infective type. The urine is sterile but contains pus cells in fair quantity with an occasional red cell. X-rays of the kidney (fig. 1) show once more a definite shadow in the right upper calix in addition to the opacities in the lower and middle calices, and an intravenous pyelogram (fig. 2) shows the same degree of dilatation in the calices.

In this case: (1) Are we dealing with mobile renal calculi or fixed calcifications in the kidney substance? (2) Is the condition in any way associated with immobilization, the patient having been kept in bed for treatment of the spondylitis? (3) Has the kidney condition any connexion with infection, as the patient had acute cystitis, although at the time this occurred the calcification was well marked? (4) Immediately before the development of cystitis the patient was in the Middle East and therefore the possible effect of a hot climate has to be considered. In addition, she had received considerable heat treatment for her backache. (5) Lastly, can we find any indications in her case of a disordered metabolism? Under this heading are included hyperparathyroidism, hypervitaminosis D, hypovitaminosis A, toxins and maladjusted diet.

I will now discuss these various possibilities in more detail.

When I use the term mobile renal calculus, I refer to a stone which can migrate within the drainage system of the calices and renal pelvis, being of variable size but usually of such a size as to be capable of temporarily obstructing the ureter in its attempt to reach the bladder, and thereby predisposing to dilatation and stasis behind it, with an ever-present invitation to coincident infection. By fixed calcification I mean a condition which is well illustrated by the following case, which I reported to this Section in November 1934.

A woman aged 44 attended St. Thomas's Hospital in January 1934 with a three months' history of dragging pain in the left lumbar region. X-rays showed an irregular group of shadows in the lower pole. The urine was normal and cystoscopy revealed no abnormality. Pyelography showed the shadows to be in the lower pole of the kidney, outside the pelvis and without dilatation of the calices. Nine months later the patient was readmitted still complaining of pain, and it was decided to explore the kidney. There was well-marked perinephritis over the area involved, at which point the cortex was slightly depressed, yellowish in colour and gritty on section. The rest of the kidney, pelvis and ureter appeared normal. I removed the kidney on the supposition that it was tuberculous and I did not feel justified in carrying out a partial nephrectomy. Macroscopically there was a wedge-shaped area containing small calculi imbedded in the renal tissue and firmly adherent. Microscopic sections showed degeneration and chronic fibrosis of the kidney with dilatation of the tubules in the region of the calculi. Prior to operation the patient had been taking a well-balanced diet and had not had any excess of alkali. There was no evidence of disorder of the parathyroid glands, the plasma phosphate being 2·4 mg.% and the serum calcium 10·2 mg.%. Two years later, the patient was perfectly fit; but the pain was unrelieved. It is obvious that it would have been wiser to have treated the patient conservatively or performed a partial nephrectomy of the ischæmic area to avoid the potential development of renal hypertension.

Further, this type of calcification is different from that usually seen in tuberculosis, in which there is always evidence of destruction of one or more calices on pyelography and a less well-defined calcification, points discussed in detail by Sandrey before this Section in 1938. Nevertheless, Randall has recorded one very interesting case in which this type of intratubular calcification occurred outside the tuberculous area and was presumably due to the effect of the toxin on the surrounding tubules. Intratubular calcification is brought about by an excessive excretion of calcium phosphate and actual deposition in the walls of the tubules by degenerative changes in them associated with defective blood supply or toxic irritants. Experimental ligation of the renal artery and injection of mercuric chloride produce this change, as do hypovitaminosis A, hyperparathyroidism and specific toxins. The exact relationship of such calcification, Randall's Type II, to the interstitial papillary calcium plaque, Randall's Type I, is not perfectly clear, although it is conceivable that they are manifestations of the same phenomenon, that is to say, the response of the kidney to toxins, the lesion depending on the intensity, frequency and length of time the organ is subjected to their influence.

At this stage it might be well to emphasize some of Randall's findings. In investigating 1,154 autopsies he discovered subepithelial papillary calcium plaques in 19·6% and in 6·5% true renal calculi originating from plaques, that is Type I calculi. Further, in a series of 265 primary calculi voided naturally, facets of origin from a papilla were obvious in 40%. Calcium deposition occurred in a relatively avascular and devitalized area in the interstitial tissue of the papilla beneath the epithelium, sometimes being deposited in rings round the basement membrane of the collecting tubules also. No evidence of infection was present and the calcium was constantly combined in the form of calcium nucleinate and not in any other form. Subsequently the covering epithelium necrosed, exposing the plaque to urine in the calix, and a secondary deposition of calcium phosphate, calcium oxalate, or uric acid occurred. He found that his Type II intratubular calcification occurred in 1·9%, or with only a tenth of the frequency of Type I. The condition usually affected a wide area of the kidney and multiple papillæ, and in 4 of the total 23 cases true renal calculi were originating from the papillary tubular matter. In 19 cases calcium phosphate was the precipitated salt and in 4 uric acid. All grades of involvement were found and in some cases isolated intrarenal calculi. Similar examples are the uratic inspissation of infants, the calcium infarction of Henle and the nephrocalcinosis of Albright. The condition had been suspected by Huggins (1933) to be a precursor of stone and Lubarsch has pointed out that, while the calcium is usually intratubular, it may also be extratubular in the cells and especially the collagenic membrane. Infection is not a primary feature and Randall suggests that the term calcium inspissation of the collecting tubules is a better one.

Type II calculi are definitely associated with the hyperexcretory state in which the colloid crystallized balance of the urine is upset. Underlying causes are (1) supersaturation with crystalloids such as oxamide or sulphonamide, (2) hypovitaminosis A and hyperparathyroidism, and (3) urea-splitting organisms in the urine.

Decubitus calculi, recumbency stones or stones associated with immobilization develop at a rapid rate in patients who are immobilized in the supine position, and are due to stasis alone. Therefore the importance of postural drainage of the kidneys has been stressed by many writers including Ogier Ward and Boyd. Rotation of the patient on to the face for some hours during the course of the day—particularly if associated with active diuresis—drains the calices and should be carried out unless it is impossible owing to retention splints. Pulvertaft (1939) recording 60 cases, mainly of bone and joint tubercle, pointed out that this difficulty can be overcome with an anterior plaster shell. The tendency to precipitation is very much increased when calcium metabolism is upset, partly by the inevitable disuse atrophy of bone and by bone disease or bone trauma. Often an unsuitable diet with an alkaline ash base has been given and there has been insufficient stress on fluid intake. Recumbency stones are composed primarily of calcium phosphate, soft and coralline in structure and situated in the most dependent calices. They tend to disperse fairly rapidly if the kidney can be flushed by getting the patient out of bed. This type of stone is a definite problem in the traumatic surgery of war, when recumbency with bone injury is commonplace. An important feature of such calculi is that they may be extremely silent in their early stages during which they are most easily dispersed. In Boyd's paper, 3 of the 4 cases he records were associated with anterior poliomyelitis, and I have such a case under my care at the present time. Here the stasis in the kidney due to deficient respiratory movements is probably a factor. A small boy of 8 with infantile paralysis developed hæmaturia and X-ray showed multiple coralline stones in the left kidney. An I.V.P. showed these to be in the calices rather than in the cortex. Flocks (1945) pointed out the necessity for repeated X-ray investigation in recumbent cases. Examination should be carried out at intervals of one, two, three and six months after the onset of the primary condition. Higgins (1940) emphasized the need for an acid ash diet fortified if necessary by ammonium salts, pointing out that the normally acid urine becomes rapidly alkaline on immobilization. He also pointed out the undesirability of prescribing mineral oil aperients as these lead to deficient absorption of vitamin A. Injudicious and faulty instrumentation of the urethra may at any time introduce infection, and if urea-splitting organisms gain a foothold disastrous results may supervene. The failure to detect decubitus stones in their early stages has impressed me in cases of this type with which I have had to deal.

The relationship of infection to stone formation appears at first sight to resemble the fable of the hen and the egg. To simplify the problem, it is well, following Randall, to discard cases where calcification is found accompanying grossly diseased states of the kidney such as calculous pyonephrosis, chronic pyelonephritis with alkaline incrustations and simple calculi of long duration. The view is generally held to-day that at various times the kidney excretes living bacteria, that these produce changes in the renal tissue which may resolve completely, and that in the absence of obstruction chronic infection of the renal pelvis is most unlikely. The close relationship between infection and stone is brought about by the following facts: (1) Infection upsets the colloid crystalloid balance (Keyser, 1923); (2) it produces epithelial clumps which form nuclei for crystallization (Eisenstaedt, 1931); (3) it may produce papillitis (Aschoff, 1913); (4) living bacteria have been found in and cultured from the centre of calculi (Hryntschak, 1935; Hellstrom, 1936); (5) urea-splitting organisms produce calcium phosphate precipitation, as urea has definite solvent properties for this salt (Hellstrom, 1929). There is also the work of Rosenow and Meisser (1922) on specific streptococci cultured from the urine of patients with calculus, which some investigators, however, have been unable to substantiate.

Randall has carried out some extremely interesting work bearing on this point. He investigated 75 cases in which obstructing calculi were removed by open ureterolithotomy, cultures being made from the urine in the obstructed renal pelvis by preliminary aspiration. He found that in 48% the urine was sterile although ideal conditions prevailed for the growth of any organism present, while in the 52% in which the urine was infected 15 different varieties of organisms were isolated and in only 38% were staphylococci present. This conflicts with Hellstrom's postulate of at least 75% of urea-splitting staphylococci. Randall failed to find evidence of infection in his histological investigation of kidneys showing calcium plaques or intratubular inspissation. He did, however, demonstrate that the kidney is susceptible to bacterial toxins, excreting them and concentrating them in so doing. If a definite strength were reached, then the renal tissue suffered damage, the damage being most marked in the collecting tubules.

An interesting and well-substantiated observation is the fact that the organisms in the kidney urine may change from time to time; on one occasion, for example, proving to be *B. coli com.*, on another *B. lactis aerogenes* and later *B. coli* again. This suggests that the kidney urine varies considerably and that organisms absorbed from the bowel and excreted may or may not find conditions favourable to their growth, similar conditions having an opposite effect on other organisms.

The onset of tuberculosis in a kidney following preliminary obstruction by a calculus appears to be very rare, but I think this occurred in the following case:

A girl aged 5 developed tuberculous caries of the cervical spine in August 1931, and was treated by immobilization until February 1934. In May 1934 the disease became active again and further immobilization was instituted. In July 1934 transitory paraplegia developed and in November leftsided lumbar pain was complained of for the first time, but there were no urinary symptoms. The left kidney was palpable but there were no abnormal constituents in the urine. No tubercle bacilli could be found in the urine, sputum or stools. X-ray investigation showed old disease in both lungs and upper dorsal caries. The I.V.P. showed a well-developed calculus at the left ureteropelvic junction with an enlarged functionless kidney above it, whilst on the right side the kidney appeared normal in shape and function. At operation I found a phosphatic stone which I submit was of the decubitus type blocking the top of the ureter with ulcero-cavernous tuberculosis of the whole kidney, necessitating nephrectomy.

The influence of prolonged exposure to heat and sun in hot climates on the incidence of renal calculus brings out some interesting points. White races appear to have a higher susceptibility than black. Vermooten (1941), reporting on one million South African negroes admitted to hospital, found only one case of renal calculus, and the American negro, while not immune, shows a much lower incidence than the white. Pierlo and Bloom (1945) found that under desert conditions in the American Army among a group of men with adequate diet, but drinking hard water, and without pathological lesions in the genito-urinary tract, the ratio of white to coloured stone cases was 10 to 1. This upsets a dietetic causation which might operate in the African negro whose diet is deficient in calcium in spite of which the teeth and bones are perfect. Quinland (1945) investigated 16,000 hospital cases among American negroes, and found only 17 instances of stone in the upper urinary tract.

Turning now to the most important or metabolic factor in the causation of stone, we have first to consider the effect of disordered parathyroid activity. Calculi associated with hyperparathyroidism are a well-recognized group at the present time, but a point which is not so well appreciated is that they can occur without any lesions of the bony skeleton. This fact has been emphasized particularly by Albright and his associates. In a ten-year survey covering 67 cases of hyperparathyroidism they found that the typical picture of osteitis fibrosa occurred in only one-third, while in another third only mild skeletal changes were present, and in the last third no bony changes at all could be found. Albright insists that the renal changes are much more important than the osseous. Cook and Keating (1945) reported on 18 cases for the Mayo Clinic during an eighteen-month period in 1943-1944. They found that in 13 cases renal calculi were the prominent features and in the majority bone disease was minimal or absent. During the same period hyperparathyroidism was proven in 2% of all cases of renal calculus at the Clinic, but as not all calculus cases were fully investigated from this angle they consider the figure is probably higher. In many cases the stones were predominantly composed of oxalate. Foulds (1945) recorded an interesting case of bilateral renal calculi in which typical bone changes and hypophosphatæmia did not develop for eight years, although hypercalcæmia had been present for some time. In this case calcium oxalate was the predominant salt. On the experimental side Randall has produced calculi in dogs receiving parathormone and showing hypercalcæmia, finding that these calculi were of both Types I and II and that calcium deposition apart from calcium inspissation was preceded by necrotic changes in the renal tissue.

Wilder and Howell (1936) believe that there is a relationship between vitamin-D deficiency and hyperparathyroidism, vitamin D aiding in the absorption of calcium from the intestinal tract while the parathyroids mobilize it from osseous tissue.

Deficiency of vitamin A disturbs the calcium-phosphate ratio and produces changes in the epithelium of the urinary tract. Stones found under such circumstances are of Randall's Type II, starting as tubular inspissation of calcium phosphate but in prolonged hypovitaminosis severe tubular changes occur. This is probably not a very important factor at the present time in the majority of cases of stone.

The relationship of calculus in patients suffering from peptic ulcer appears well established and is readily attributable to their high intake of milk, alkalis and calcium carbonate with a resultant alkaline urine. There are, however, few statistics bearing on this particular point. Keyser (1943) stressed this fact.

Oxamide and sulphonamide calculi are obvious instances of crystallization due to the hyperexcretory state in which the colloid can no longer hold the excess crystalloid in solution.

Oxalates we have already seen are of importance as producing secondary deposition on pre-existing calcium plaques, especially if hyperoxalæmia and hyperoxaluria are present. They may occur from exogenous sources such as rhubarb or spinach, or from endogenous errors in metabolism. Oxaluria may be due to a disturbed calcium-phosphorus ratio or by incomplete oxidation of carbohydrates.

Calcium phosphorus metabolism is probably the most important factor in stone formation, as calcium figures in all the types of stone under discussion constituting the vast majority. Normal serum calcium is 9·5 to 10·5 mg.%. It is absent from the blood cells and exists as a large non-diffusible fraction combined in the serum and a small diffusible fraction in the ionized state, and varies directly with the pH of the blood, being more ionized in acid. The calcium level is influenced by parathormone, vitamin D, serum protein and the serum phosphorus, with which last it varies inversely. Hypercalcinuria is present in hyperparathyroidism, hypervitaminosis D, uræmia and many diseases of bone, the principal endogenous source of calcium: 70 to 90% is excreted in the fæces and 10 to 30% in the urine. Phosphorus normally ranges from 3 to 4 mg.% in the serum and is increased in hypoparathyroidism, hypervitaminosis D, retention nephritis and fractures. 30% of phosphorus is excreted in the fæces and 70% in the urine. Flocks investigated the relationship of stone to excessive urinary calcium excretion and found that 66% of calculus patients showed hypercalcinuria on a neutral ash diet. Normal calcium excretion is 90 to 150 mg. daily, while stone patients excreted 200 to 450 mg. on similar diet. Vitamin D and acid ash diet increase calcium elimination. An excessive chloride acidosis increases the urinary excretion of calcium and is most marked in the case of ammonium chloride, a practical point as excessive acidosis may damage the renal tubules with resultant calcification.

The metabolism of citric acid has definite relationship to the formation of renal calculi. Important contributions to this subject have been made by Scott, Huggins and Selman (1943) who pointed out that urinary citric acid runs a cyclical course with the reproductive period and that with a normal blood citrate the urinary citrate of patients with calculi was lower than normal, indicating an excessive oxidation in the kidney of citric acid in such subjects. Shorr (1945) made very interesting suggestions for the use of œstrogens and aluminium hydroxide gels in the treatment of renal stone.

Œstrogens increase the citrate excretion in the urine and lower that of the calcium. There is a definite citric acid cycle in metabolism and it is readily convertible into glycogen and glucose, participating in the oxidation of carbohydrate and fatty acids to carbon dioxide and water. Citric acid is present in large quantities in bone, where it is interrelated with calcium. The amount of urinary citric acid is regulated by, first, the urinary hydrogen-ion concentration rising in alkaline and falling in acid urine; secondly, the urinary output of calcium running *pari passu* with it; and thirdly, the sex hormones varying with the menstrual cycle, output being highest at the mid-menstrual period and lowest at menstruation. Œstrogens augment the output of citrate and androgens reduce it. The presence of the citrate-ion influences the ionization of calcium tending to replace the calcium-ion participating in the precipitation of calcium phosphate by the readily ionized soluble calcium-citrate complex, the extent of the effect depending on the relative concentration of calcium nitrate and hydrogen-ions. Below a hydrogen-ion concentration of 7 the reaction is progressively reduced, but even in acid ranges the effect of the citrate complex in removing calcium-ions is still considerable. Addition of citrate would prevent precipitation of calcium phosphate from solution, and this effect is maximal in alkaline solution in which calcium phosphate is least soluble. The effect is less in acid solution in which calcium phosphate is more soluble and requires less citric acid. This is obviously an ideal mechanism for the kidney to prevent precipitation of calcium phosphate, and it is significant that two conditions favouring precipitation, namely hypercalcinuria and an alkaline urine, are accompanied by increased excretion of citric acid. That this is a purposeful function is supported by investigating patients suffering from renal calculus. It has been shown that in many cases of recurrent renal calculi without infection subnormal amounts of citric acid and excessive amounts of calcium are present in the urine. Further, in such cases smaller amounts of orally administered citric acid are excreted than in normal controls. If infection is superadded two further unfavourable factors may arise, namely a reduction of citric acid present in the urine by the organisms which use it as a metabolite and an increased alkalinity of the urine from the organisms breaking down urea to ammonia. It is obvious that an increase in urinary citric acid excretion might prevent stone formation or check the increase of pre-existing stones. Unfortunately, feeding citric acid is useless, since however much is given by the mouth only very small increases result in the urine. If sodium citrate is given, any increase in urinary citric acid is due to increased alkalinity from the sodium-ion and is offset by the resultant reduced solubility of calcium phosphate in the alkaline urine. Œstrogens, however, increase urinary citric acid without affecting the hydrogen-ion concentration and they also lower the output of calcium. It is possible that the definitely lower incidence of renal calculus in women as opposed to men is due to this fact, the range for citric acid excretion in males lying between 0·4 and 0·7 gramme per twenty-four hours as opposed to 1·5 grammes during the mid-menstrual phase.

A further step to prevent the precipitation of calcium phosphate would be the reduction of the phosphoric-ions, and this can be brought about by administration of aluminium hydroxide gel. This forms the highly insoluble aluminium phosphate in the gut and much reduces the absorption of phosphorus. Thus the plasma phosphorus is low and with it the urinary excretion. In other words, phosphorus excretion is diverted from the kidney to the intestine. It is possible by administering aluminium hydroxide gel in amounts of 120 c.c. during twenty-four hours to reduce the urinary phosphate excretion by 90%, while still maintaining perfect calcium, phosphorus and nitrogen balance. This is especially beneficial when urea-splitting organisms are present producing highly alkaline urine with resultant diminished solubility of calcium phosphate. Acid ash diets and acidifying regimes fail when urea-splitting organisms are present, as the urine in the calices is always alkaline even if acid in the tubules. Further, renal damage is often present, which makes highly acid states dangerous. Even without infection a urinary hydrogen-ion concentration of 4·8 would be continuously necessary to dissolve a stone. Acidifying agents lower the urinary excretion of citrate and increase that of calcium, thus keeping the urine saturated and only capable of dissolving the endogenous calcium phosphate without being able to dissolve any existing calcium phosphate deposits, in other words, to inhibit further stone growth but not to remove stones already present. This helps to explain some of the disappointments in the use of stone-dissolving solutions. To summarize: Shorr suggests that it would seem probable that both œstrogens and amphojel may prove helpful in guarding against recurrent post-operative stones or the development of decubitus calculi.

TREATMENT

We can appreciate how the facts that have so far been considered have a bearing on the control of the calculus patient, particularly in the field of post-operative care. Further, that preventive treatment has to be initiated at an early stage to have any chance of success. In the case of definite renal calculi, the indications for active surgical intervention are obstruction of the drainage mechanism of the kidney either in the ureter, or renal pelvis or calices, as evidenced by dilatation shown on intravenous pyelography, with the proviso that there is no likelihood of the stone being passed naturally. Any evidence of failing function in the obstructed part or, more important, suggestion of the onset of infection, necessitates active intervention.

Non-operative treatment is indicated under the following conditions: (1) Limitation of the calculi to the cortical part of the kidney where they have no macroscopic connexion with a calix; (2) mobile stones not causing obstruction and of such a size as to make passage *per vias naturales* possible; (3) stones composed of calcium phosphate or mixed phosphatic stones; (4) bilateral stones associated with gross disease and limited function in both kidneys, rendering any operation hazardous.

Much can be done by forced fluids, by correction of faulty diet and by attempts to control superadded infection. Postural drainage may be very helpful in dislodging a stone. In the case of decubitus calculi or stones consisting wholly or largely of phosphates, attempts may be made to dissolve the calculi by the use of Suby's Solution G, and it is most important to bring this about before secondary infection supervenes, particularly with urea-splitting organisms which render the stones relatively insoluble. The continuous use of Solution G presents practical difficulties, as it necessitates the passage of a ureteric catheter over a long period of time, possibly up to two to three months, any one catheter being changed at intervals not greater than ten to fourteen days. 20 c.c. of Solution G should be injected at three-hourly intervals or some continuous irrigation apparatus used, utilizing up to 3,000 c.c. in twenty-four hours, and the desirability of using two catheters, one for inlet and one for outlet, has to be borne in mind. Sometimes dissolution will proceed satisfactorily and then be arrested owing to the stone having a part composed of some insoluble salt such as oxalate, but nevertheless it may have brought about such a reduction in size as to render the natural passage of the stone possible. Hamer (1944) recorded such a case. Another case of possible difficulty has been pointed out by Keyser. This is a slowing down or cessation of dissolution in Solution G due to the deposition of a mucoid gelatinous covering on the surface of the stone. If a 0·5% solution of urease be substituted for a few hours, this envelope is dissolved and Solution G may again prove effective.

In many cases of gross bilateral calculus disease, it is surprising how little disability the patient experiences. A patient, aged 45, had stones in both kidneys in 1933 and was operated on elsewhere. Now, in spite of gross changes he appears quite fit, has little pain and the blood urea is 43 mg.%. Obviously any operation would be extremely hazardous and could hardly improve the man's condition, while it would almost certainly render it worse.

When we return to a consideration of operative treatment, the first point that arises is the approach to the kidney, and for some fourteen years past I have favoured an incision in the line of the twelfth rib with subperiosteal resection of the rib at the posterior end of the incision. There is nothing novel in this, and I was converted to its merits by Victor Dix following the practice of Von Lichtenberg. However, I do not think its merits have been sufficiently appreciated by the majority of surgeons. Kenelm Digby recently (1941) called attention to this fact. The advantages are as follows: The incision is straight and comparatively short; it is remarkably avascular, it being quite often unnecessary to tie any vessels at all in the parietes; it is atraumatic, as it lies between the eleventh and twelfth nerves and it is as a rule unnecessary to carry the incision far forwards into the flank muscles; it gives a perfect exposure of the upper pole of the kidney, which can be explored without any undue trauma, and if necessary the suprarenal and sympathetic can also be dealt with. The pleura is far less likely to be damaged in a difficult case, and in the event of nephrectomy proving necessary it is the ideal incision. The only objection is that a second exposure of the kidney may be rendered difficult by regeneration of bone in the site of the rib.

Calculi should always be removed by pyelolithotomy if possible, and it is surprising how, with a proper exposure and suitable curved forceps to enter the calices from the pelvic incision, what a large proportion of stones can be removed in this manner. I prefer an incision in the long axis of the ureter and choose to suture the pelvic incision provided hæmostasis is complete and suture is easy, splinting the suture line with perinephric fat. On the other hand, if the pelvis is thickened and friable it is difficult and unnecessary to suture it, and I have never seen any ill-results accrue from not doing so.

Nephrolithotomy has always seemed to me an undesirable operation, and I must admit to a dread of incisions into the renal substance in order to reach an incarcerated stone. The bloodless line is a figure of speech and the suture of the kidney, even with such aids as ribbon gut and muscle or fat grafts, is not always easy. It is tempting to make the incision into the kidney with the diathermy cutting current, but this is undesirable from the long-term point of view, as it predisposes to further calcium deposition in the incised area. Even if the primary hæmorrhage is satisfactorily controlled, there is always the nightmare of secondary hæmorrhage, and it is particularly in cases where the kidney is grossly infected that nephrolithotomy is undesirable. Many of us must have had the mortifying experience of having to carry out a secondary nephrectomy in a case where a comparatively small incision has been made in the kidney substance. I have always felt that some unnecessary damage must be done to the secreting part of the kidney which is avoided in pyelolithotomy, although Mimpriss (1934) investigated this problem and could find no evidence of renal impairment after splitting the kidney. As opposed to this, Gray (1936) in experimental work on dogs found serious damage in 5 out of 12 cases.

The following case illustrates some of these points:

A woman aged 57 in 1934 had pain in the right flank, and an examination of the urine showed pus cells and *B. proteus*. A pelvic operation had been carried out many years before, and apart from a history of dental sepsis nothing was discovered in the past history. X-rays showed bilateral cortical renal calculi with a stone apparently in the upper right calix. Renal function was excellent and the blood calcium normal. Attempts were made to control the infection in the urinary tract without effect, and in 1935 (fig. 3) the small stone in the right upper calix had grown and filled the right pelvis, urine from which grew *B. proteus* on culture. I therefore removed this stone by pyelolithotomy, without any difficulty. Inadvisedly I removed the cluster of stones near the lowest calix by

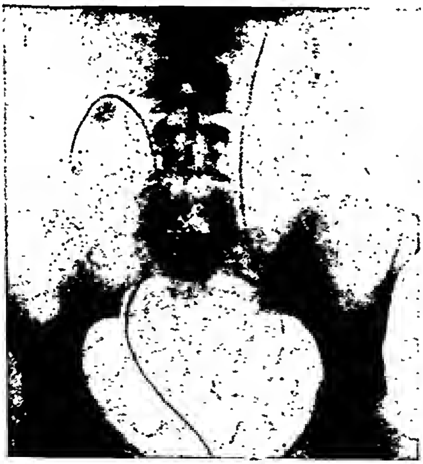

FIG. 3.—Cortical stones with large secondary stone in pelvis.

splitting the lower pole to ascertain their nature, and because I was not certain they were all fixed in the renal tissue. All seemed to be proceeding very well until the twelfth day, when she suddenly had profuse hæmorrhage into the wound and into the bladder with high fever. A transfusion and secondary nephrectomy were carried out, the kidney being offensive and necrotic in the area of the incision. Three months later the urine was reported sterile. Four years later, however, she reported with pain in the left loin and a coralline stone in the renal pelvis of the remaining kidney. Pyelolithotomy with avoidance of the cortical stones would have been wisest.

An interesting problem is whether or not to put in a nephrostomy tube after removing a renal stone, and I think on this point there is some difference between American and British practice. I consider that, in cases where dilatation has resulted from the presence of a stone, a nephrostomy tube can do no harm and may do good, and is extremely useful if lavage of the pelvis should be necessary. It is essential that drainage should be from the dependent point of the lowest calix, preferably by Cabot's method. More information is needed on the effects of nephrostomy, and I have been disappointed in the lack of recovery in the kidney which is often seen after the removal of a stone. Probably this is largely a question of the degree of infection and damage to the kidney prior to operation.

The following case is that of a man aged 27 in 1942 who had right renal colic, and in 1943 a stone was removed from the right kidney, following which operation he developed a lumbar abscess which had to be drained and he was considered unfit for further military service. He reported persistent turbidity of the urine with no other symptom. Investigation in February 1943 showed a large stone in the left kidney, with fair function and good function on the right (fig. 4). Urine was sterile but contained pus cells. Renal function was good and there was no leucocytosis. For domestic reasons operation was postponed until September 1943, during which interval he had no symptoms whatever. Operation revealed a calculous pyonephrosis and a branched stone which I removed by pyelolithotomy followed by nephrostomy and closure of the pyelolithotomy wound. Twenty-eight days later, urine from the left kidney was sterile on ureteric catheterization. Six weeks later I removed the nephrostomy tube. Seven months later he was fit, with sterile urine, but little function in the left kidney (fig. 5).

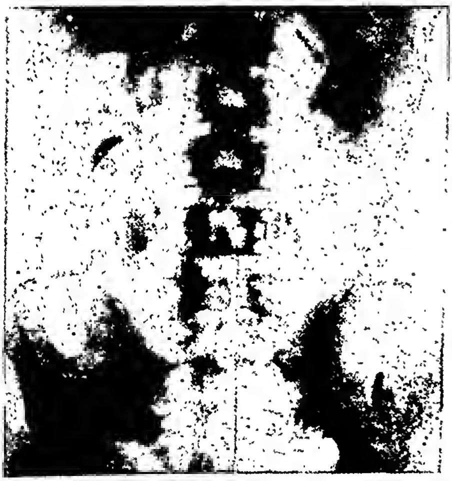

FIG. 4.—Large stone in left kidney. Good function.

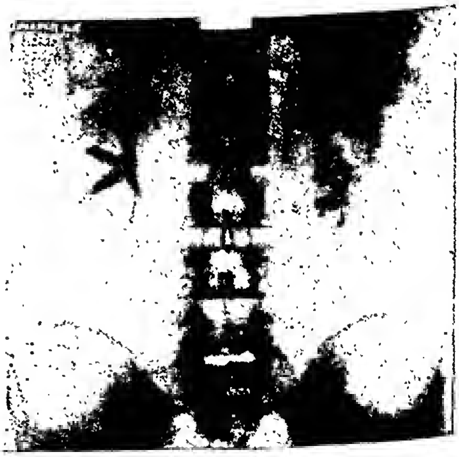

FIG. 5.—Poor function after removal of calculus.

I would emphasize again the value of a nephrostomy tube in enabling the renal pelvis to be irrigated by the two-way method with an indwelling catheter, and all evidence goes to show that this method should give the best results with stone-dissolving solutions.

I have no personal experience of the method advocated by Dees (1946) for avoiding the danger of overlooking small fragments of a branched calculus when performing a pyelolithotomy, namely by utilizing an intrapelvic coagulum of thrombin and human fibrinogen for their extraction.

The following case illustrates a more practical point in pyelolithotomy, the patient being a woman of 40 with left renal colic and hæmaturia. X-ray showed a catheter had passed easily above the stone, which was therefore unlikely to be in the ureter or ureteropelvic junction. Lateral X-ray showed the bougie in front of the stone and a pyelogram indicated a horseshoe kidney, with the stone in the lowest left calix, which was confirmed by intravenous pyelography.

In horseshoe kidney the renal pelvis lies in front and is approached in front of the renal mass in contradistinction to the usual approach from behind. I have found the operation comparatively simple if this point is borne in mind.

Calicectomy or partial nephrectomy may be used, particularly when a ragged cavity remains in the lower pole of the kidney after removal of a stone, in which case recurrence is only too likely. In a clearly incised and accurately approximated area of renal tissue, post-operative hæmorrhage is less likely than in a ragged infected cavity round a calculus.

Cases of bilateral stone require considerable judgment in deciding whether to operate at all or which side to approach first. Most surgeons are opposed to simultaneous bilateral operation, although Hryntschak reported a series of cases in which he had done so without fatality.

Nephrectomy or even nephro-ureterectomy may prove the wisest course, as the infected calculous kidney seldom if ever returns to complete normality. The presence of a dilated pelvis with residual urine in it and fibrosis in and around its walls means the inevitability of urinary infection. When, however, the disease is bilateral, conservative surgery, even if it leaves a second-rate kidney in the end, may be the only possibility. The following case illustrates this point:

A woman aged 45 complained of lumbar pain in the left side of four years' duration. She appeared a poor surgical risk with myocardial degeneration. The renal efficiency was gravely impaired and both kidneys appeared to be equally affected. The urine showed pus and triple phosphates, with a growth of enterococci on culture.

The pre-operative X-ray and the pre-operative retrograde pyelogram showed multiple stones in a dilated renal pelvis. I performed a pyelolithotomy which passed off uneventfully, and the post-operative retrograde pyelogram, two months after, showed appreciable but incomplete recovery.

URETERIC CALCULI

The indications for active surgical intervention in the case of ureteric calculus are the same as in the case of renal calculus, that is to say dilatation of the upper urinary tract above the stone, particularly if infection is superadded. If infection is present without dilatation, one should always be suspicious of further disease apart from the presenting stone in the ureter.

If neither dilatation nor infection is present, a conservative attitude can be adopted indefinitely, provided the patient is kept under close observation. Equally well, it is surprising the rate at which an obstructed kidney may become totally destroyed once infection gains a foothold. It is disturbing that these points are not better appreciated even in surgical circles, and many books of reference give an arbitrary time of six weeks for the natural passage of a ureteric calculus, which is utterly meaningless and a most dangerous doctrine.

Let me quote two cases illustrative of these points.

In March 1936 I saw a patient aged 68 who had had his right kidney removed nine years previously for calculous pyonephrosis. Three weeks prior to my seeing him he had had a brisk attack of left renal colic with some vesical irritation. He remained perfectly well with a good urinary output. X-rays showed a stone near the bladder, with good renal function. Six months later, as the stone was still present, I cystoscoped him with some misgiving, as he had a large prostate, and passed a catheter up to the kidney, alongside the stone, tying it in for forty-eight hours. There was no reaction, but it was not until six months later that the stone passed. During the whole of this time he remained perfectly fit and without any evidence of infection.

A man of 36 had a sharp attack of right renal colic, and X-ray investigation showed three stones in the lowest calix. Intravenous pyelography showed a generalized dilatation of the pelvis and calices, suggesting that the obstructing stone must have dropped back into the lowest calix. Shortly afterwards a second attack of colic developed, and unfortunately, in spite of severe and persistent pain together with fever, he was not sent up to hospital for three weeks. X-ray then showed one of the three stones impacted in the upper ureter and a complete absence of function in an enlarged kidney. When I exposed the kidney, I found it pyonephrotic and disorganized, necessitating nephrectomy.

A point of the greatest practical importance is the site of impaction of ureteric calculi, and in my experience this occurs usually either in the abdominal segment between the second and third lumbar vertebræ or on the pelvic floor in the last two inches of the ureter. Of the two the pelvic position is considerably the commoner.

The prognosis and treatment are very different in the two instances. In the case of a stone impacted in the abdominal segment of the ureter, obstruction to the secretion of urine is usually well marked and for some reason further progress seldom occurs. It is true that most of the cases seen are instances of spiculated oxalate calculi tending to imbed themselves in the ureteric mucosa, but it would appear as though there were some anatomical factor which, having once arrested the stone, makes its further progress unlikely. Some interesting observations on the relative absence of nerves in this part of the ureter have recently been made by Emerson Smith and Strasberg (1942). Spontaneous retreat of a calculus back up to the kidney is also rare, unless the stone happens to have a smooth surface, and particularly in cases where the whole ureter is dilated. Moore (1946) records such a case.

An interesting case illustrating this and other phenomena was that of a soldier aged 25, blown up in a jeep in April 1945. He was unconscious for a week, having sustained a fractured base and in addition injuries necessitating a bilateral above-knee amputation and a suprapubic cystostomy. Both stumps suppurated and his condition was critical. Two months later the suprapubic wound was allowed to heal and, although micturition was free, cystitis persisted. On November 16 he experienced left renal colic with a temperature of 103°, a palpable kidney and *B. coli* in the urine. X-rays seven days later, on November 23 (fig. 6), showed a round stone between the transverse processes of the second and third lumbar vertebræ, blocking the ureter, which is dilated above and collapsed below the stone, but demonstrates fair function in the kidney. The temperature subsided suddenly with relief of pain, and on November 26, three days later, X-ray (fig. 7) showed that the stone had retreated into the renal pelvis, appearing to have increased slightly in size. The urine now grew *B. lactis aerogenes* on culture. In view of the limb condition, no active surgical treatment was possible. On December 13 he was fit, but X-ray showed the round stone lying in the lowest calix with fair renal function but spasm of the ureter below the site of the original obstruction. On January 10, 1946, X-ray showed the same picture with improved renal function. He remained fit from the kidney point of view until March 8, when he had a further attack of left renal colic associated with fever lasting a week, the urine now growing *B. coli* again. An X-ray at this stage showed that a small oval secondary stone lay in the ureter opposite the transverse process of the

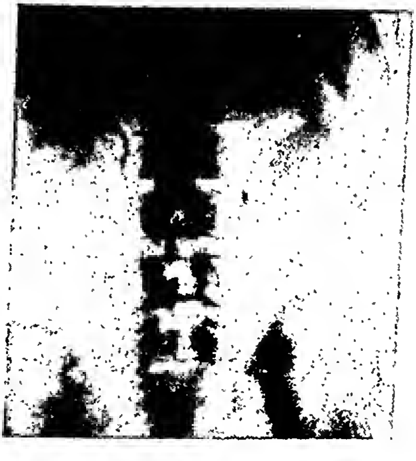

FIG. 6.—Stone in upper ureter.

fourth lumbar vertebra and that the original stone had grown considerably, partially filling the renal pelvis. An X-ray on March 22 showed some progress of the ureteric stone and fair function in the kidney without obvious dilatation. On May 7 he passed the ureteric calculus spontaneously and he has remained fit since, but X-ray on July 2 showed a well-defined branched stone which will have to be removed as soon as his general condition permits. Renal function is good on intravenous pyelography (fig. 8), but there is definite dilatation which can also be observed in some degree on the other, sound side.

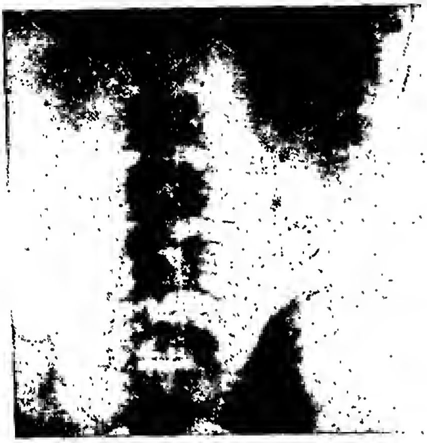

FIG. 7.—Stone passed back into renal pelvis.

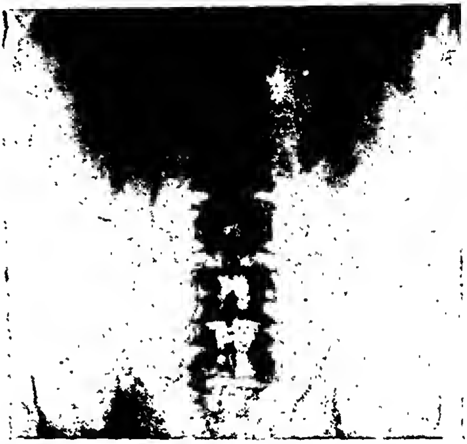

FIG. 8.—Good renal function. Large stone in left renal pelvis.

This case demonstrates first that a smooth ureteric stone can retreat into the renal pelvis, thereby relieving obstruction of the kidney; secondly, the rapid rate at which a renal calculus can grow in the presence of infection and obstruction, and the effects of continued infection on the kidney.

Retreat of a ureteric calculus may sometimes be brought about by preliminary investigations, and this fact emphasizes the importance of X-ray control immediately before or, preferably, if necessary during operation.

A woman aged 44 had left renal colic, and X-ray investigation revealed an oxalate stone blocking the top of the left ureter. A retrograde pyelogram confirmed this (fig. 9), showing a slight leak back above the stone. Some hours later, just prior to my operating upon her (fig. 10), the stone was visible in the lowest calix, from which it was easily removed by pyelolithotomy, but it might have proved difficult to find without the preliminary guide of an X-ray film.

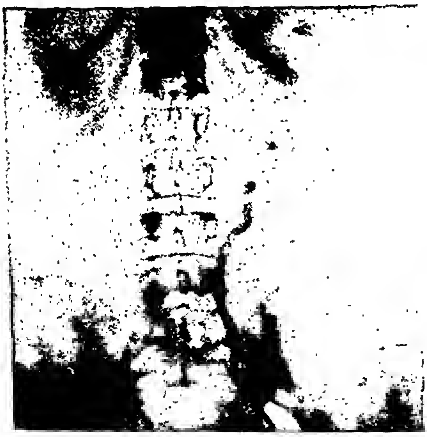

FIG. 9.—Calculus in upper ureter.

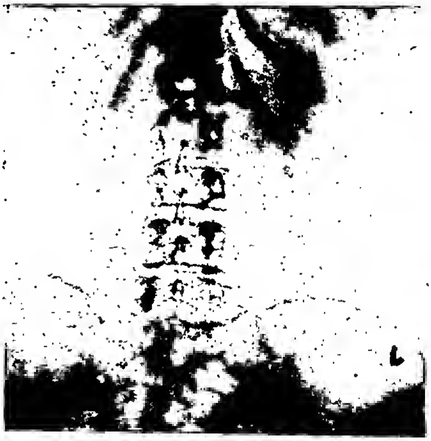

FIG. 10.—Same calculus in lowest calix.

suggesting that the obstructing stone must have dropped back into the lowest calix. Shortly afterwards a second attack of colic developed, and unfortunately, in spite of severe and persistent pain together with fever, he was not sent up to hospital for three weeks. X-ray then showed one of the three stones impacted in the upper ureter and a complete absence of function in an enlarged kidney. When I exposed the kidney, I found it pyonephrotic and disorganized, necessitating nephrectomy.

A point of the greatest practical importance is the site of impaction of ureteric calculi, and in my experience this occurs usually either in the abdominal segment between the second and third lumbar vertebræ or on the pelvic floor in the last two inches of the ureter. Of the two the pelvic position is considerably the commoner.

The prognosis and treatment are very different in the two instances. In the case of a stone impacted in the abdominal segment of the ureter, obstruction to the secretion of urine is usually well marked and for some reason further progress seldom occurs. It is true that most of the cases seen are instances of spiculated oxalate calculi tending to imbed themselves in the ureteric mucosa, but it would appear as though there were some anatomical factor which, having once arrested the stone, makes its further progress unlikely. Some interesting observations on the relative absence of nerves in this part of the ureter have recently been made by Emerson Smith and Strasberg (1942). Spontaneous retreat of a calculus back up to the kidney is also rare, unless the stone happens to have a smooth surface, and particularly in cases where the whole ureter is dilated. Moore (1946) records such a case.

An interesting case illustrating this and other phenomena was that of a soldier aged 25, blown up in a jeep in April 1945. He was unconscious for a week, having sustained a fractured base and in addition injuries necessitating a bilateral above-knee amputation and a suprapubic cystostomy. Both stumps suppurated and his condition was critical. Two months later the suprapubic wound was allowed to heal and, although micturition was free, cystitis persisted. On November 16 he experienced left renal colic with a temperature of 103°, a palpable kidney and *B. coli* in the urine. X-rays seven days later, on November 23 (fig. 6), showed a round stone between the transverse processes of the second and third lumbar vertebræ, blocking the ureter, which is dilated above and collapsed below the stone, but demonstrates fair function in the kidney. The temperature subsided suddenly with relief of pain, and on November 26, three days later, X-ray (fig. 7) showed that the stone had retreated into the renal pelvis, appearing to have increased slightly in size. The urine now grew *B. lactis aerogenes* on culture. In view of the limb condition, no active surgical treatment was possible. On December 13 he was fit, but X-ray showed the round stone lying in the lowest calix with fair renal function but spasm of the ureter below the site of the original obstruction. On January 10, 1946, X-ray showed the same picture with improved renal function. He remained fit from the kidney point of view until March 8, when he had a further attack of left renal colic associated with fever lasting a week, the urine now growing *B. coli* again. An X-ray at this stage showed that a small oval secondary stone lay in the ureter opposite the transverse process of the

for. It is surprising that it is not better appreciated that the pains associated with ureteric calculi are due to distension of an obstructed renal pelvis above and not to the onward passage of a stone, which is painless and can only occur when the ureter is relaxed. Of the instrumental methods, I have found the use of an indwelling ureteric catheter passed alongside the stone and kept in situ for forty-eight hours the most satisfactory method. If the Howard corkscrew or the Councill umbrella extractor is used, it is always wise to insert an indwelling ureteric catheter to counteract the effects of reactionary œdema. Personally I confess to being very apprehensive of their use, although I am well aware of the spectacular results that have been achieved. Wishard (1943) reported some unfortunate experiences with the basket extractor, and Dourmashkin (1945), reporting on a most exhaustive study of the cystoscopic treatment of 1,550 cases of ureteric calculus, advised against the use of forcible mechanical extraction. Councill himself (1945) recorded three instances of rupture of the ureter in a series of 504 cases. Actual meatotomy of the ureteric orifice is seldom necessary and is better avoided because of the risks of troublesome hæmorrhage and, more important, ureteric incompetence with vesicorenal reflux. If instrumentation fails, operation is called for and I have used both the mid-line and inguinal approaches. Of these the inguinal is simpler and quicker provided that the stone is not too low, in which case the mid-line approach is essential. It is accepted as axiomatic that the approach should always be extraperitoneal, but I would suggest that this is incorrect and that under certain circumstances transperitoneal approach may have great advantages, particularly in women.

On one occasion I set out to remove a stone from the lower end of the ureter by a mid-line extraperitoneal exposure, and found extreme difficulty in obtaining any adequate approach. It became obvious that a pelvic tumour was present, rendering the identification of the ureter impossible. I therefore opened the peritoneum and found a bilateral pyosalpinx, undoubtedly the underlying cause of the urinary condition, for which I carried out a bilateral salpingectomy. As a result, the ureter with the contained stone was well exposed, enabling me to open it and remove the calculus. Wishing to ensure free drainage from the kidney and to avoid extravasation of urine, I passed the fluted end of a ureteric catheter through the incision in the ureter up to the renal pelvis, subsequently passing the lower end down the ureter and through the ureteric orifice into the bladder in which the redundant part coiled up. I then sutured the ureter over the catheter and passed a stab extraperitoneal drain down to the suture line through a fresh incision in the flank. The peritoneum was then sutured over the ureter and the abdomen closed. Four days later I cystoscoped the patient and withdrew the catheter with duckbill forceps. I was so impressed with the smoothness of this patient's convalescence that I have repeated this procedure in several cases where it appeared desirable, one of which I reported in 1938.

In those cases of ureteric calculus where infection exists in the obstructed kidney behind the stone (and, according to Randall, that is in roughly 50% of cases) I have often observed a brisk flare in clinical cystitis after removal of the stone. Appreciating this fact, it is wise to culture the kidney urine and give a post-operative course of sulphonamide, if necessary.

In the case of the pelvic portion of the ureter, spontaneous passage of calculi occurs in a very high proportion of cases—in my experience 90%—although some time may be taken in the process, as in the case I quoted earlier where twelve months elapsed. Retrograde movement may occur, but usually only when hydroureter co-exists, and if planning operation this fact should be borne in mind when tilting the patient on the operating table, as it is possible to roll the stones up and down the ureter by force of gravity. In my experience the necessity for operative interference is lower among the educated sections of the community, probably because they seek medical advice at an earlier stage.

A diagnostic point of interest to be remembered is that the lower end of the ureter may lie in or very near the middle line. The original report in one case was three stones in the bladder, but on cystoscopy only one was visible, which I removed. The patient returned some months later, and subsequently X-ray showed the two remaining shadows in the bladder and considerably increased in size. They were also crushed and removed.

When we consider the actual operative technique for the removal of ureteric calculi, it can be said that in the case of calculi in the abdominal segment any form of cystoscopic removal is inadvisable and dangerous, the problem being one of open surgery. As a rule a short muscle-splitting incision below the kidney will expose the peritoneum, which is displaced forwards revealing the ureter containing the impacted stone. The ureter should be controlled above and below to prevent the possibility of the stone slipping back, and an incision made in the long axis of the ureter over the stone, which is removed. If the incision can be closed with one or two catgut sutures which approximate the edges without transgressing the lumen, I consider this ideal, although it is not essential, as provided that there is no obstruction to the ureter below, the major part of the urine will pass down into the bladder. In my experience post-operative stricture will only occur if the mucosa has been destroyed by pressure ulceration due to the calculus, in which case the kidney will usually have been rendered functionless and require removal. Some surgeons are very much opposed to suture, as they consider free drainage of the kidney essential, and if there is any doubt about the state of the ureter it is probably best to drain it with a T tube round which regeneration may take place, thereby avoiding stricture.

Obviously some œdema of the ureteric wall must occur in the early post-operative period, which may interfere with renal function and it is interesting to note what does take place.

A boy aged 12 was admitted in February 1936 with a history of right renal colic and hæmaturia three weeks previously. The pre-operative X-ray showed a small stone impacted in the abdominal segment of the right ureter with an early hydronephrosis above it, the left side being normal. I removed the stone by lumbar extraperitoneal lithotomy, suturing the ureter. Ten days after the operation, the boy had a sharp attack of abdominal pain most marked on the opposite side. X-ray now showed a considerable increase in the hydronephrosis on the operated side and a definite hydronephrosis on the sound side. The boy had no further pain and he was discharged fit and well on the fifteenth post-operative day. X-rays taken six weeks later showed both kidneys to be normal. Wells (1935) commented on the length of time taken over recovery.

When dealing with calculi in the pelvic segment of the ureter, open operation is very much a last resort. In many cases forced fluids alone suffice, and it is surprising how often cystoscopy is quickly followed by the passage of a stone. This happens so frequently that it cannot be mere coincidence, and it may be due to the dilatation of the posterior urethra leading to a reflex relaxation of the intramural part of the ureter. This occurs without the patient being aware of it, and very often the stone is voided unwittingly, which indicates how desirable it is for all urine to be passed under conditions where the expected calculus can be searched for. It is surprising that it is not better appreciated that the pains associated with ureteric calculi are due to distension of an obstructed renal pelvis above and not to the onward passage of a stone, which is painless and can only occur when the ureter is relaxed. Of the instrumental methods, I have found the use of an indwelling ureteric catheter passed alongside the stone and kept in situ for forty-eight hours the most satisfactory method. If the Howard corkscrew or the Councill umbrella extractor is used, it is always wise to insert an indwelling ureteric catheter to counteract the effects of reactionary œdema. Personally I confess to being very apprehensive of their use, although I am well aware of the spectacular results that have been achieved. Wishard (1943) reported some unfortunate experiences with the basket extractor, and Dourmashkin (1945), reporting on a most exhaustive study of the cystoscopic treatment of 1,550 cases of ureteric calculus, advised against the use of forcible mechanical extraction. Councill himself (1945) recorded three instances of rupture of the ureter in a series of 504 cases. Actual meatotomy of the ureteric orifice is seldom necessary and is better avoided because of the risks of troublesome hæmorrhage and, more important, ureteric incompetence with vesico-renal reflux. If instrumentation fails, operation is called for and I have used both the mid-line and inguinal approaches. Of these the inguinal is simpler and quicker provided that the stone is not too low, in which case the mid-line approach is essential. It is accepted as axiomatic that the approach should always be extraperitoneal, but I would suggest that this is incorrect and that under certain circumstances transperitoneal approach may have great advantages, particularly in women.

On one occasion I set out to remove a stone from the lower end of the ureter by a mid-line extraperitoneal exposure, and found extreme difficulty in obtaining any adequate approach. It became obvious that a pelvic tumour was present, rendering the identification of the ureter impossible. I therefore opened the peritoneum and found a bilateral pyosalpinx, undoubtedly the underlying cause of the urinary condition, for which I carried out a bilateral salpingectomy. As a result, the ureter with the contained stone was well exposed, enabling me to open it and remove the calculus. Wishing to ensure free drainage from the kidney and to avoid extravasation of urine, I passed the fluted end of a ureteric catheter through the incision in the ureter up to the renal pelvis, subsequently passing the lower end down the ureter and through the ureteric orifice into the bladder in which the redundant part coiled up. I then sutured the ureter over the catheter and passed a stab extraperitoneal drain down to the suture line through a fresh incision in the flank. The peritoneum was then sutured over the ureter and the abdomen closed. Four days later I cystoscoped the patient and withdrew the catheter with duckbill forceps. I was so impressed with the smoothness of this patient's convalescence that I have repeated this procedure in several cases where it appeared desirable, one of which I reported in 1938.

In those cases of ureteric calculus where infection exists in the obstructed kidney behind the stone (and, according to Randall, that is in roughly 50% of cases) I have often observed a brisk flare in clinical cystitis after removal of the stone. Appreciating this fact, it is wise to culture the kidney urine and give a post-operative course of sulphonamide, if necessary.

ABSTRACT.—There are many problems concerning the ætiology, diagnosis and treatment of stone which are still unsolved. The exact relationship between Randall's type I calculus formed as a papillary plaque and therefore liable to be passed naturally at an early stage of development and the type II formed as an intratubular deposition is obscure. It is possible that they are both due to the response of the kidney to toxins, the exact lesion depending on the intensity, frequency and length of time the organ is subjected to their influence. A variety of factors contribute to stone formation, such as the hyperexcretory state with an upset of the colloid crystalloid balance in the urine, recumbency with immobilization, infection, climatic conditions and disordered metabolism. Calcium and phosphorus metabolism and their disorders are vitally concerned in calculus formation. Recent work on citric acid metabolism and its alterations due to hormonic influence point the way to efficient prophylaxis. Œstrogens increase the excretion of citrate in the urine and lower that of calcium. Addition of citrate prevents precipitation of calcium phosphate from solution, an effect which is maximal in alkaline solution in which calcium phosphate is least soluble. This is an ideal mechanism for the kidney to prevent the precipitation of calcium phosphate. Reduction of phosphate ions would enhance this effect and such reduction may be produced by the administration of aluminium hydroxide gel which forms insoluble aluminium phosphate in the gut.

Treatment of calculi may be non-operative or surgical. Obstruction and infection call for prompt surgical relief. Non-operative treatment can be advised under the following conditions: (1) Limitation of calculi to the cortical part of the kidney. (2) Mobile stones of such a size as to render natural passage possible and not causing obstruction. (3) Stones composed of calcium phosphate or mixed phosphates and therefore capable of spontaneous or therapeutic solution. (4) Bilateral stones associated with limited function and disease affecting both kidneys, rendering operation hazardous.

Forced fluids, the correction of faulty diet and the control of infection may be of great assistance. Postural drainage should be tried and in addition in the case of phosphatic stones, Suby's solution G.

When operation becomes necessary, an exposure of the kidney through an incision in the line of the twelfth rib with resection of that structure may prove extremely helpful. Pyelolithotomy is the preferable method of removing stones and in most cases this method is practicable with adequate exposure. Incisions into the cortical part of the kidney should be avoided unless absolutely essential to effect removal of a calculus. Nephrostomy is worthy of more extended trial but in unilateral cases with gross infection nephrectomy or even nephro-ureterectomy may prove the best treatment.

Most ureteric calculi are eventually voided naturally although cystoscopic manipulation may be necessary if stones are retained in the pelvic portion of the ureter. Mechanical extractors should be used with considerable caution. Operative technique should be varied to suit the individual case and illustrative cases demonstrating these points are described.

In all cases post-operative follow-up and suitable prophylaxis are most important if improvement in recurrence rate is to be brought about.

RÉSUMÉ.—Beaucoup de problèmes concernant l'étiologie, le diagnostic et le traitement de la lithiase restent à résoudre. Les relations précises entre le calcul du type I de Randall, formé comme plaque papillaire, et tendant par conséquent à être expulsé par les voies naturelles à un stage précoce de son développement, et le type II, formé comme dépot intratubulaire, sont obscures. Tous deux sont peut-être dus à une réaction du rein à l'action de toxines, la forme précise de la lésion dépendant de l'intensité, de la fréquence et de la durée de leur influence sur l'organe. Plusieurs facteurs contribuent à la formation des calculs, par exemple l'état hyperexcrétoire, accompagné d'un dérangement de l'équilibre colloïde crystalloïde de l'urine, la position couchée avec immobilisation, les infections,

les conditions météorologiques et les troubles du métabolisme. Les métabolismes du calcium et du phosphore et leurs dérangements sont de toute première importance pour la formation des calculs. Des travaux récents sur le mètabolisme de l'acide citrique et ses variations sous l'influence des hormones indiquent le chemin vers une prophylaxie effective. Les œstrogênes augmentent l'excrêtion urinaire des citrates et diminuent celle du calcium. L'addition de citrates empèche la prècipitation du phosphate de calcium d'une solution. Cet effet est au maximum en solution alcaline, où la solubilité du phosphate de calcium est au minimum. Ce mécanisme est idéal pour le rein pour empêcher la précipitation du phosphate de calcium. La réduction des ions phosphate augmenterait cet effet, et une telle réduction est possible par l'administration d'hydrate d'aluminium colloïde, qui produit du phosphate d'aluminium insoluble dans l'intestin.

Le traitement de la lithiase peut être opèratoire ou non. L'obstruction et l'infection réclament l'intervention chirurgicale prompte. Un traitement non-opératoire peut être recommandé dans les conditions suivantes: 1° Calculs limités à la partie corticale du rein, 2° Calculs mobiles de grandeur adaptée à l'expulsion par les voies naturelles, et ne produisant pas d'obstruction. 3° Calculs composés de phosphate de calcium ou d'une mélange de phosphates, et par conséquent capables d'être dissous spontanément ou par un traitement médicamenteux. 4° Calculs bilatéraux avec fonction rénale réduite et maladie atteignant les deux reins, ce qui rend l'opération dangereuse.

Les liquides forcés, la correction d'un régime défectueux et les mesures anti-infectieuses peuvent beaucoup aider. Le drainage postural doit être essayé et, en plus, dans les cas de calculs phosphatiques, la solution G de Suby.

Quand l'opération devient nécessaire, la mise à nu du rein par une incision parallèle à la 12e côte, avec résection de cet os, peut être extrêmement utile. La pyélo-lithotomie, qui est possible dans la plupart des cas si la mise à jour est suffisante, est la meilleure opération pour l'extraction des calculs. Les incisions de la partie corticale doivent être évitées à moins qu'elles ne soient absolument nécessaires pour enlever un calcul. Il vaudrait la peine de continuer les expériences de la néphrostomie, mais pour les cas unilatéraux la néphrectomie ou même la néphro-urétérectomie peut être le meilleur traitement.

La plupart des calculs urétéraux finissent par être expulsés par les voies naturelles, mais une manœuvre cystoscopique peut devenir nécessaire si les calculs sont retenus dans l'uretère pelvien. L'emploi des extracteurs mécaniques doit être accompagné de grandes précautions. La technique opératoire doit être variée selon les cas. Cet avis est illustré par la description de quelques cas.

Dans tous les cas l'observation post-opératoire et un traitement prophylactique approprié sont essentiels pour réduire la proportion de récidives.

Sumario.—Aun existen para aclarar muchos problemas de la etiologia, el diagnóstico y el tratamiento de la litiasis. Es obscura la relación exacta entre el calculo tipo I de Randall, que se forma como una placa papilar y por consiguiente es sujeto a ser evacuado por la naturaleza tempranamente en su producción, y el tipo II que se forma como un depósito intratubular. Es posible que ambos resultan de la reaccion del riñon a toxinas, la lesión exacta dependiendo de la intensidad, la frequencia y la duración del tiempo que el órgano esta expuesto a su influencia. Una variedad de factores contribuyen a la formación del calculo, como el estado hiperexcretorio acompañado por un trastorno del equilibrio coloide cristaloide en la orina, la inmovilización en cama, una infección, condiciónes climáticas y desordenes metabolicos. El metabolismo del calcio y del fósforo y sus desordenes son de primera importancia en la formacion del calculo. Estudios de origen reciente sobre el metabolismo del acido citrico y las alteraciónes que causan en este las hormonas indican el camino a una profilaxis eficaz. Los oestrogenes aumentan la excreción de citrato en la orina y disminuyen la de calcio. La añadidura de citrato impede la precipitacion de calcio fosforado de la solución, un efecto que es máximo en una solucion alcalina en laque el calcio fosforado es el minimo soluble. Esto ofrece al riñon un mecanismo ideal para prevenir la precipitación del calcio fosforado. La reducción de los iones de fosforo aumentaria este efecto y tal reducción puede ser producida por la administración del hidróxido de aluminio gel que forma en el intestino el aluminio fosforado insoluble. El tratamiento de casos de calculo puede ser terapeútico o quirúrgico. Una obstrucción o una infección exige la intervención quirúrgica inmediata. El tratamiento terapeútico es aconsejado sobre las condiciónes siguientes : (1) Cuando los calculos son limitados a la parte cortical del riñon. (2) Cuando los calculos son movibles y de tal tamaño que es possible evacuarlos naturalmente y que no causan una obstrucción. (3) Calculos del fosforado de calcio o de fosforados mezclados por esto capables de solución espontánea o terapeútica. (4) Calculos bilaterales acompañados de una limitacion de función y una condición patológica en los dos riñones, que haria arriesgada una operación.

La receta de liquidos en gran cantidad, la rectificación de alimentos defectuosos y la restricción de infecciónes pueden ser de gran ayuda. Se debe probar el drenaje postural y tambien además la solucion G de Suby en los casos con calculos fosforados.

Cuando una operación es necessaria, es muy provechoso exponer el riñon por una incisión en la linea de la costilla duodécima con resección desta estructura. Pielolitotomía es el método preferible para sacar los calculos y en la mayoría de casos este método es practicable si se emplea una exposición adecuada. Se deben evitar las incisiones en la parte cortical del riñon si no son absolutamente

esencial para sacar el calculo. Es justo probar la nefrostomia en mas casos pero en casos en que un riñon solo esta afectado y la infección es densa la nefrectomía o mismo la nefro-ureterectomia puede salir el mejor tratamiento.

La mayoría de los calculos uretericos se evacúan naturalmente con el tiempo aunque una manipulacion cistoscopica puede ser necesaria si los calculos son retenidos en el uréter pélvico. Extractores mecánicos se deben emplear con una cautela considerable. Se debe variar la técnica de operación segun cada caso individuo. Se incluyen en este estudio casos ilustrativos.

Es de primer importancia en todos los casos examinarlos de vez en cuando despues del tratamiento quirúrgico estar completo y exigir una profilaxia apropiada si una mejoría en la proporcion de reincidencias va ser efectuada.

АВСТРАКТ.—Многие проблемы, которые касаются этиологии, диагноза и лечения камней почек до сих пор еще не разрешены. Точная зависимость между первым типом камней (по Рандалю), которые образуются ввиде папиллярной бляки и потому могут быть выделены естественным путем в раннем периоде образования и вторым типом камней, которые образуются ввиде интратубулярного отложения, — вовсе не ясна. Возможно, что оба типа являются следствием влияния токсинов на почку и точное поражение почки зависит от тяжести, частоты и продолжения их действия на орган. Множество факторов предрасполагает к образованию камней, как например, гиперэкскреторное состояние с нарушением коллоидо-кристаллоидного равновесие в моче, лежачее положение с иммобилизацией, инфекция, климат или нарушенный метаболизм. Метаболизм кальция и фосфора и нарушение этого метаболизма являются весьма важным фактором в образовании камней. Самые недавние работы над метаболизмом лимонной кислоты и его изменением под влиянием гормонов, указывают на путь к успешной профилактике. Острогены увеличивают выделение цитратов в моче и уменьшают выделение кальция. Прибавление цитратов предотвращает осадок фосфата кальция из раствора, что происходит в высшей степени в щелочном растворе, в котором фосфат кальция хуже всего растворяется. Для предупреждения осадка фосфата кальция, это является идеальным механизмом для почки. Редукция фосфатных ионов увеличит этот эффект и такую редукцию можно произвести применением жела гидроокиси алюминия, который образует нерастворимый фосфат алюминия в кишках.

Лечение камней может быть нехирургическим и хирургическим. Обструкция и инфекция требуют немедленного хирургического вмешательства. Нехирургическое лечение необходимо при следующих условиях:--

(1) Присутствие камня в кортикальной части почки.
(2) Подвижные камни такого размера, что их естественный проход возможен и не произведет обструкции.
(3) Камни фосфата кальция или смешанных фосфатов с возможностью самопроизвольного или терапевтического растворения.
(4) Двухсторонние камни, связанные с ограниченной функцией и болезнь обоих почек, при которой операция слишком рискованна.

Большое количество жидкостей, исправление неправильной диэты и контроль инфекции — весьма важны. Постуральный дренаж должен быть испробован, а также раствор „G“Суби при фосфатных камнях.

Когда операция становится необходимой, обнажение почки через надрез по линии 12-го ребла с его резекцией — может быть весьма полезным. Пиэлолитотомия — более предпочтительный метод удаления камней и в большинстве случаев он возможен при достаточном обнажении почки. Нужно избегать надрезов кортикальной части почки, за исключением тех случаев, когда это необходимо для удаления камней. Нефростомия должна быть испробована более часто, но при односторонних случаях с сильной инфекцией, нефректомия или даже нефро-уретеректомия, является лучшим способом.

Большинство камней мочеточника обыкновенно выделяются естественным путем, хотя цитоскопическая манипуляция может быть нужна в тех случаях, когда камни задержаны в тазовой части мочеточника. Механические экстракторы должны быть применяемы с большой осторожностью. Операционная техника должна быть приноровлена к индивидуальным случаям. Автор здесь приводит иллюстрации для указания таких случаев.

Все больные должны быть подвергнуты наблюдению после операции. Для избежания рецидивов весьма важна соответственная профилактика.

DISCUSSION ON THE TREATMENT AND PROGNOSIS OF TRAUMATIC PARAPLEGIA

Dr. L. Guttmann: The institution in this country of Spinal Units during the recent war was the first step forward in the systematic study of the problem of rehabilitation of spinal cord casualties, who, in the past, have been considered all too often as unemployable, useless and hopeless cripples. In this paper, a short account is given on the work carried out in the Spinal Injuries Centre, Ministry of Pensions' Hospital, Stoke Mandeville, since February 1944, on 177 casualties, out of a total number of 210 spinal cord lesions—108 were caused by gunshot injuries, 69 by fractures. 119 cases were cord lesions, the details of which are given in Table I. Of 58 cases showing cauda equina lesions, 51 involved lumbo-sacral roots and 7 sacral roots only.

The cases were admitted at varying intervals after injury, from First Aid Posts, military and E.M.S. hospitals, &c. In numerous cases, their condition was serious, owing either to the initial injury, with gaping wounds, discharging cerebrospinal fluid, or to associated injuries to other organs—in particular, lungs or extremities. In the majority of cases, the spinal lesions were complicated by contractures of the paralysed limbs. Many cases admitted at later dates showed signs of aseptic absorption with pneumonia and emaciation resulting from multiple pressure sores, urinary infection or infections of other organs. In another group of these late arrivals, where the physical condition was not unsatisfactory, the mental condition was poor. Therefore, treatment had to be very active and multifarious.

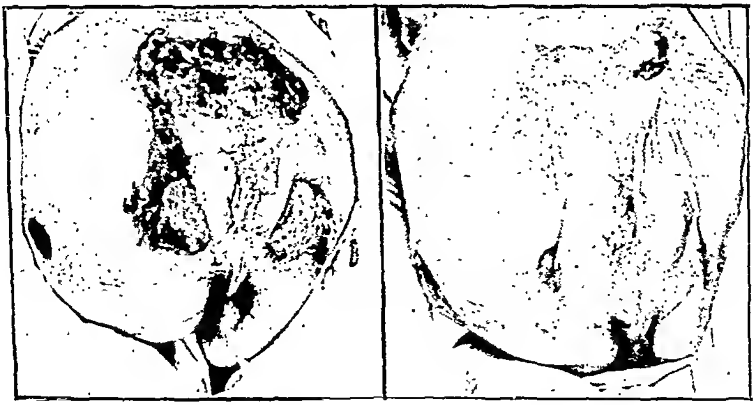

Fig. 1.

The problem of the care of the skin and the treatment of bedsores—that most serious complication which, apart from urinary infection, is the commonest cause of sepsis and death after spinal injury—has been described in detail elsewhere (Guttmann, 1945, 1946). Most of the patients arrived with multiple bedsores, some of them of gigantic and grotesque dimensions. Experience in this Centre has shown that bedsores literally as big as soup plates and exposing the bone can heal in a surprisingly short time. Fig. 1 demonstrates the stage of healing of large sacral and buttock sores four months after commencement of treatment.

Care of bladder.—Ascending urinary infection from the paralysed bladder is the other main cause of sepsis and death in spinal cord lesions and represents a problem which, in spite of all efforts and discussions on local treatment, is still unsolved. It is beyond the scope of this paper to go into details of all the various local methods which are employed to counteract urinary infection, but at least the two main procedures—namely, suprapubic cystotomy and urethral catheterization—may be evaluated. From the author's personal observations it would appear that neither urethral catheterization nor suprapubic cystotomy has yet proved a safeguard against ascending urinary infection.

Most of the cases arrived at this Centre with a suprapubic cystotomy already performed. We were, therefore, no longer in a position to decide whether any other method could have been suitably applied, for instance in incomplete lesions. As shown in Table II, suprapubic cystotomy was carried out in 148 cases, and in 112 of these within the first three days after injury. Every case with suprapubic cystotomy, whether with or without previous urethral catheterization, showed signs of urinary infection, and in a considerable number of cases the infection of the urinary tract was of severe type, including pyrexial attacks, epididymo-orchitis, stone formation in bladder, ureters and kidneys, leading to pyo- and hydronephrosis. As can be expected, the infection is introduced and maintained by the suprapubic tube, especially if the tube is left in the bladder for several weeks and has become encrusted with phosphates. Systematic and simultaneous bacteriological investigations of urine specimens and culture swabs taken from the bladder end of the catheter have repeatedly shown that the catheter contained bacteria other than those found in the urine specimen (Table III)—for instance, hæmolytic streptococci, staphylococci and *B. proteus*. The danger of transferring virulent organisms from the infected suprapubic catheter through the bladder and open ureters directly into the pelves and calices must be considerable, in view of the fact that the cystogram repeatedly revealed a reflux into ureters and kidneys in certain cases of cord and cauda equina lesions. In this connexion, it may be noted that we

have encountered several cases where frequent pyrexial attacks, due to urinary infection, ceased when the suprapubic drainage was discontinued.

In cases of middle or upper thoracic lesions the bladder was found extremely contracted. Moreover, once the uninhibited automatic function of the bladder has developed, suprapubic cystotomy does not prevent reflex detrusor action of the infected urine through the urethra and thus does not prevent the development of epididymo-orchitis. These facts show that there is no reason to consider suprapubic cystotomy as *the method of choice* in the treatment of every case of paralysed bladder. Judging from war experience, it has proved valuable only as an emergency measure on the battle-field, when immediate transfer of spinal injuries to adequate hospitals was impossible. Under peacetime conditions, the prompt transfer of a paraplegic to a Spinal Centre should be practicable in almost every case, and this appears to be the best guarantee for a more specialized treatment of the paralysed bladder. There are instances in which suprapubic drainage is indicated and is even preferable to urethral drainage as the lesser evil of the two—in particular, in cases with narrow urethra, urethral strictures and other local urethral injury, and in some with special nursing problems. Further experience will show whether Riches' special method of suprapubic catheterization (1943) is preferable to the open suprapubic cystotomy.

Tidal drainage has proved a valuable auxiliary method in a number of our cases, especially in the early stages after cord and cauda equina lesions, in cases both with suprapubic drainage and indwelling urethral catheter. This may be emphasized, in view of the fact that, during the last two years, the enthusiasm for this method, as instigated by Munro, 1936, has somewhat waned. This method was found of special value for removing mucus and small stones from the bladder, the latter especially from the posterior wall, if the patient is placed in prone position. However, it must be admitted that this method is of use only if it is understood by everyone concerned, including the patient, and is constantly supervised. In certain cases of small bladders, with uninhibited detrusor activity, in cord lesions, and also in some cases of cauda equina lesions with rigid bladder walls, tidal drainage has not worked satisfactorily, in spite of all efforts. The apparatus used in this Centre is that designed by Riches (1943), which has the advantage of being equipped with a manometer and can be used for cystometrograms. The fluids used for irrigation are ½% acetic acid, 4% boric acid and flavazole 1 : 2,000. In cases with stone formation, we have used solution G (Suby, Suby and Albright, 1942). However, our experience with this solution has proved less satisfactory, and from the rehabilitation point of view the author prefers instrumental removal of calculi from the urinary tract by a skilled urologist, as this is the safest and quickest method of removal. Once calculi are removed, we carry on with solution G for a certain period.

The development of automatic reflex activity of the bladder wall in spinal cord lesions and voluntary micturition by pressure of the abdominal wall in lower cord and cauda equina lesions are encouraged and exercised, as recommended in the Great War by Riddoch (1918). Whenever practicable, suprapubic drainage is discontinued. This has so far been carried out in 94 cases out of 148 at various intervals. Healing of the suprapubic wound is often delayed by the profound fibrosis of the suprapubic tract, and even surgical closure by excision of the tract and resuture does not always prevent the breaking down of the tract, especially in cases with low suprapubic cystotomy and those in which suprapubic drainage was discontinued at later dates. When suprapubic drainage is discontinued, it is necessary, especially during the first period after discontinuation, to continue bladder washouts intermittently by urethral catheterization at various intervals, or by temporary drainage with an indwelling catheter of small size. By this procedure, we have even succeeded in rendering the urine, infected by suprapubic cystotomy, sterile in a few cases. In this Centre, intermittent urethral catheterization and continuous catheterization, the latter if combined with tidal drainage, and with change of indwelling catheter every two to four days, have proved satisfactory. In cases in which urethritis develops, the bladder washout has to be combined with washouts of the urethra itself with flavazole solution 1:2,000. Paraplegics with long narrow foreskins tend to develop balanitis, and it is better in these cases to carry out circumcision, or at least a dorsal slit, as soon as possible.

Pyrexial attacks, due to urinary infections, are counteracted by courses of sulphonamides and systemic courses of penicillin.

Whatever local methods in the treatment of paralysed bladders are used, two of the main factors in the treatment, in particular for prevention of stone formation, are the *shortening of the duration of the recumbent position and the restoring of the best possible physical fitness of the man.* The former is more feasible in cases of gunshot injury and fractures of transverse and spinous processes with spinal cord involvement, as the support of the spine has not been interfered with in the majority of cases.

EFFECTS OF BLADDER DISTENSION ON AUTONOMIC MECHANISMS.

In connexion with the care and treatment of the bladder after spinal cord injuries, certain reflex reactions in the autonomic nervous system must be mentioned, which are set up by distension of the bladder (and this applies also to rectum and colon) due to any cause, as these phenomena are not only of interest from a theoretical point of view, but have practical importance. Some of these phenomena have been previously observed: they have, for instance, been mentioned in Head and Riddoch's classical study on mass reflexes (1917), and in more recent years studied experimentally by Carmichael *et al.* (1939).

During studies on sweating, in relation to bladder distension in spinal cord lesions, my attention was drawn to various other reflex responses. Several patients with complete upper thoracic lesions, on distension of the bladder, which did not give rise to any sensation of pain below the level of the lesion, developed patchy flushing of face and neck, profuse localized sweating over head and shoulders or at the level of the lesion, blockage of nasal air passage and nasal voice, a slow pulse with occasional extrasystoles, respiratory discomfort, and fullness in the head, which progressed to severe occipital or frontal headaches. It was at once realized that this was a phenomenon of autonomic mechanisms, in which a stimulus arising from a distended viscus below the level of a complete spinal cord lesion effected, along extramedullary pathways, profound disturbances of the cardiovascular activity in parts of the body above the level of the lesion. In order to investigate and record all the details involved in this reflex phenomenon, a research team was organized with Dr. Whitteridge and his colleagues from the Physiological Department, Oxford, and we examined vasomotor response and heat regulation by measuring skin temperatures below and above the level of the lesion, in relation to rectal temperature, sweating, blood-pressure, pulse volume and blood-flow, pulse-rate, respiration, and conscious sensation. It was found that these reflex responses were dependent in consistency and intensity on the level of the lesion. They were most conspicuous in all complete lesions of the cervical and upper thoracic cord down to T. 5—in other words, in those lesions in which the greater part of the splanchnic control was crippled. In such cases, the rise of blood-pressure due to bladder distension was high, and values of 190-260 mm.Hg of systolic and 125 to 135 mm.Hg of diastolic blood-pressure were recorded. Further details will be given in Dr. Whitteridge's report and a full description of our work will be published shortly elsewhere.

From a practical point of view, knowledge of these reflex responses above the level of a cord lesion is important, as they indicate abnormal activity of a viscus in the anæsthetic area below the level of the lesion. They can be diagnosed simply from facial appearance, and their recognition by medical and nursing staff will be a guide for immediate and correct action. Moreover, they explain why complaints of headaches and fullness in the head in paraplegics have always to be considered seriously, as they may be a warning of impending abdominal catastrophe.

PHYSICAL REHABILITATION

Physiotherapy in paraplegics, to be effective for restoring the man's fitness to the highest possible degree for independence, working capacity and family life, must be applied early and practised persistently. The aims of physiotherapy can be divided into two main groups:

(1) *Prevention of contractures and atrophy and treatment of the various forms of spasms.*—The methods employed include keeping the limbs in the correct position, passive movements, bath therapy, and surgical procedures. Permanent fixation of paralysed limbs in any position is discouraged. The most deleterious type of contractures was found in cases admitted in plaster beds, in which patients had lain for months. Not only have plaster beds proved no better method for preventing and healing sores, for which they were previously advocated, but they have actually promoted the development of sores. Moreover, the contractures of the joints and the atrophy of the tissue of the back, caused by this type of fixation, were profound, and it took a very long time to remedy the damage done. Therefore, plaster beds must be condemned as being contrary to the fundamentals of rehabilitation in paraplegics.

In relation to the prevention and treatment of flexor spasms, the importance of the various intrinsic and extrinsic factors in lowering the threshold of reflex activity of the part of the spinal cord below the level of the lesion may be emphasized. Distension of bladder, colon and rectum, and the irritation of sensory organs in contracted joints and tendons are violent initiators of reflex spasms. Regular passive movements have proved most beneficial in the treatment of spasms. Even extreme degrees of flexor spasms and contractures may be greatly improved by this conservative method, especially if the passive movements are carried out in a continuous bath. The importance of standing exercises in parallel bars for the relaxation of spasms, apparently by setting up inhibitory impulses to the unrestrained activity of the flexor groups, may also be mentioned here.

Surgical measures for the treatment of spasms, especially anterior root sections, should be restricted to selected cases. In such cases, intramedullary alcohol injections—1 to 2 c.c. of 80% alcohol—into the thoraco-lumbar junction of the cord, using a fine needle, may be tried first, as being the less arduous method. The immediate effect of such an injection in abolishing the most violent flexor spasms can be very striking, as shown in a case of complete lesion at T. 10 (fig. 2). However, the first injections had only a temporary effect in our three cases, and further injections had to be given, in order to produce a more lasting effect. Further experience with this method will be published in the near future.

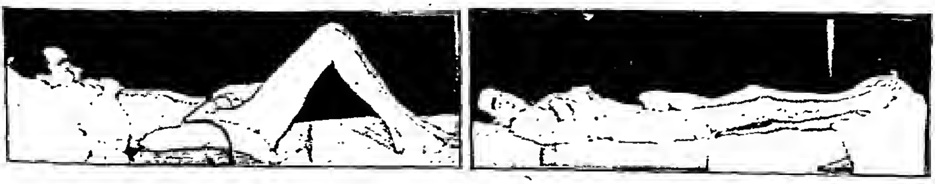

FIG. 2.—Effect of intramedullary alcohol injection into the thoraco-lumbar junction of the cord, in a patient with a transverse lesion at T. 10 and violent flexor spasms.

(2) *Adaptation therapy of normal parts of the body by compensatory training.*—Exercises of normal parts of the body are carried out with a view to readjustment of the vasomotor control to postural changes and to the over-development of those muscles which are essential for the patient's upright position, as well as those which have a synergic function in relation to the paralysed muscles and can compensate for their loss. Details of the technique of compensatory training, in which sling and spring exercises, dressing, balancing, walking exercises and games, adapted to the paraplegic's limited abilities, have proved invaluable, have been published elsewhere (Guttmann, 1946). We have found, in confirmation of previous experimental work (Hill and Barnard, 1897 and others) that gravity has a profound effect upon the blood circulation, especially blood-pressure, in cases of high thoracic and cervical lesions, in which the vasomotor control is crippled. Such a patient, when raised to the upright position, will tolerate this position badly. However, if well trained, he develops postural adaptation mechanisms, which may be regulated by carotid sinus and other blood collectors to act as "emergency adaptors".

PREVOCATIONAL TRAINING AND RESETTLEMENT

Along with physical readjustment goes rehabilitation by work. This is started with occupational therapy in the form of simple handicrafts, whilst the patients are confined to bed because of sores and urinary infection. This therapy is not merely occupation as a diversional measure—it is invaluable for the development of the dexterity of the fingers and arms, upon which the future vocation of a paraplegic will depend. As soon as possible, prevocational training is added. It includes leather-work, precision engineering, clock assembly, shoe repair, carpentry, typing and shorthand, and correspondence courses in various trades. This work is graded and correlated to the physical improvement of the man and to his previous personality. The benches and tools in the workshops are adjusted to the individual patient's disability. Most of the men have shown keen interest in prevocational training, either to readjust their former trades to their permanent disability or to take up training in a new occupation. Indeed, early vocational training in hospital has proved to be most useful as a step forwards in the social rehabilitation of paraplegics and has restored activity of mind.

In relation to domestic and industrial resettlement, one has to distinguish between two groups of paraplegics. The first group consists of those patients who will not be able to return to their homes. For these men, permanent settlements adapted to their disabilities will be established, in which married and unmarried patients can live in sheltered conditions and from which they can go out in their wheel chairs to their places of employment. Those who are not able to go out to work will have an opportunity of doing work which will be adjusted to their disabilities in the settlements. The first of such settlements, which has been opened recently with patients from this Centre, is situated near Macclesfield and is run by the British Red Cross Organization.

Another group of patients will be able, and will prefer, to return to their homes, if these can be adjusted to their disabilities, or if special bungalows can be built for them. The British Legion is already co-operating in this work. 48 out of 84 patients discharged from this Centre have returned to their homes, and 29 of these are working. 36 patients were transferred to special convalescent homes set up at Chaseley, Eastbourne, and the Star and Garter Home, Richmond, pending their admission to permanent settlements or training centres, or return to their own homes.

It is at present rather premature to make definite statements about the ultimate survival period of paraplegics of the recent war. However, judging from our own cases, it has been proved that at least the early mortality after spinal cord injury is much lower than one would expect from the statistics of World War I. In our statistics of 164 survivors out of 177 cases (Table IV), all but 2 were cases from

TABLE IV

the recent war. It should be noted that our low mortality statistics include 3 cases in which death was obviously caused by injuries and pathological process of other organs (lungs in 2 cases, heart in 1 case).

In conclusion, it can be said that the results achieved in the rehabilitation of paraplegics are very encouraging, in so far as the medical problem is concerned. However, there is much more to be done for their social and industrial rehabilitation. In particular, there is still great need to adjust the attitude of the public towards the permanent disability of paraplegics. Any condition which maintains or induces a sense of inferiority should be avoided. These men do not look for charity but for understanding assistance in their efforts to master their disability and adjust themselves to life again. "Adjust or perish"—that fundamental principle in the universe, which enables the weaker to master life and to compete successfully with the stronger, can be applied in its full meaning to the rehabilitation of paraplegics.

Mr. E. W. Riches: I propose to confine my remarks to the treatment of the urinary tract.

A lesion producing complete interruption of the spinal cord or cauda equina causes paralysis of the bladder; the stages through which this viscus passes are essentially the same for all injuries causing paraplegia. They are (1) complete retention; (2) retention with overflow or passive incontinence; (3) periodic reflex micturition. After incomplete or transient interruption a state of voluntary micturition differing little from the normal may ensue.

The aim of treatment is to leave the urinary tract free from infection, with a bladder of adequate capacity from which urine can be passed without incontinence, preferably by the natural passage. The initial treatment of the bladder is of great importance; if it is correct it may well suffice as the line of treatment throughout; if it is wrong it may condemn the patient to urinary sepsis and early death.

The first essential is to drain the bladder; this does not mean that drainage must be carried out immediately. The former teaching that the bladder should be emptied by catheter as soon as possible after the injury is harmful. The bladder should be allowed to distend, and this will usually take at least twenty-four hours and often more. It can safely be left for thirty-six or forty-eight hours without being emptied if it is not infected. It will not rupture, it will overflow, and distension for two days will not produce such impairment of function as to preclude ultimate complete recovery. The recognition of this fact obviates the need for immediate drainage and allows time for the patient to be moved to suitable surgical surroundings. Failure to recognize it often leads to urethral catheterization under poor conditions, and serious infection follows in almost every case when urethral catheterization is continued for more than two days. It is true that there are rare cases in which the retention is painful, and if the pain is not relieved by morphia it is then permissible to empty the bladder by aspiration through a serum needle inserted well above the pubes. This may if necessary be repeated once, but frequent aspiration is likely to lead to extravasation. Under peacetime conditions however it should rarely be impossible to get the patient into hospital within twenty-four hours; during the war mobile teams often made surgical treatment available in a shorter time.

Let us then assume that twenty-four hours have elapsed, the bladder is distended, there has been no voluntary or automatic micturition and the surroundings are such that reasonable asepsis is possible. Is the bladder to be drained by urethral or suprapubic catheter? I may say at once that I strongly advocate the suprapubic route for general use. It is true that we have had one or two cases received into the Spinal Injuries Centre at Stoke Mandeville very soon after their injury where the urethral catheter combined with tidal drainage and adjuvant measures have been used successfully, but they form a very small minority. They require infinite care and unlimited time, and their supervision is a one-man job. Incidentally paraplegics should never be catheterized by an orderly. When drainage is established it must be adequate and regular or continuous; it must be such as to prevent extreme contraction or excessive dilatation of the bladder, there must be no urinary leakage, and above all it must avoid the possibility of serious infection. The method must be one which the nursing staff can understand and care for. The method I advocate is the introduction of a small suprapubic catheter into the upper part of the distended bladder. Its track must be oblique, and the catheter must fit closely. I do not refer to suprapubic cystotomy as usually performed. We all have often been horrified by the large tube placed at the bottom of a long incision with urine leaking around it and infection getting in. At a later stage the track becomes adherent to the pubes and closure is at best delayed and at worst impossible. Moreover the bladder is allowed to contract down to a small capacity, and any periodic reflex micturition which may ultimately develop is useless because of its frequency. Examples have been shown previously (Riches, 1944).

I have described elsewhere the method of suprapubic catheterization (Riches, 1943*a*, *b*); the small catheter, size 16F, is inserted into the distended bladder through a small incision in the abdominal wall. Its point of entry is opposite the highest point of bladder dullness or the mid-point between the umbilicus and the symphysis, whichever is the lower. Its direction is obliquely downwards and backwards. It is rapid, requires no great technical skill but only a modicum of common sense, and is quite safe provided that the bladder is distended. If this is not the case the bladder must be exposed through a short incision before the catheter is introduced. The catheter must be changed after fourteen days and subsequently once a week. Any straight rubber catheter of the same size can be used and no introducer is required, the only necessity being asepsis. If the catheter is to be retained for many weeks it is replaced by one a little larger, size 20F being usually adopted.

Cases treated by this method have proved satisfactory, and it would appear that the principle of suprapubic drainage is not at fault.

TIDAL DRAINAGE

When drainage has been established it must be continuous; any obstruction of the catheter will make it act as a cork and will be followed by signs of infection. This applies particularly to cases previously infected by urethral catheterization. The best way of ensuring continuity is by efficient tidal drainage. The apparatus we use, the "double Y", is convenient because it incorporates a cystometer. An irrigating fluid designed to keep the urine acid is preferable. Where there is a tendency to phosphatic deposition the solution G of Suby (1942) is of most value.

The value of tidal drainage has been questioned by those who maintain that small doses of sulphonamides are more effective in preventing infection. Unfortunately sulphonamides cannot be continued indefinitely whilst tidal drainage can. To me one of the most encouraging facts about it is that of the few men discharged with permanent suprapubic tubes most continue to keep their tidal drainage going every night.

It is often asked why suprapubic drainage gives less liability to serious infection than urethral drainage. It may be stated at once that suprapubic drainage does not prevent infection of the bladder; whenever a tube is passed into the bladder and retained there infection is bound to gain entrance in time. With a catheter in the urethra, however, there is always urethritis and it has been shown that the path of ascending infection is by direct lymphatic spread from the deep urethra by peri-ureteral lymphatics to the kidneys. There is no such direct lymphatic connexion from the track of a suprapubic catheter to the kidneys, and ascending infection is much less common from a bladder which is draining freely. Infection of the bladder is not lethal but infection of the kidneys is.

The effect of inadequate drainage.—The policy of absolute non-interference with the bladder has been advocated from time to time, the bladder being left alone until the stage of retention with overflow is followed by automatic micturition. This certainly obviates the risk of instrumental infection but it does carry the dangers of prolonged overdistension. The time before periodic reflex micturition is established is uncertain and may be more than a year in cauda equina lesions and serious renal damage may ensue if the bladder is not drained. Perhaps the worst danger lies in irregular intermittent catheterization which leads to infection without securing continuous drainage.

A woman of 25 developed a cauda equina lesion following a spinal anæsthetic. She was catheterized occasionally but allowed to go home with urinary incontinence, before periodic reflex micturition was established. I saw her six months later when she had a distended bladder with overflow incontinence and gross urinary infection. The right kidney was hardly secreting, the left was dilated, and the bladder held 17 oz. (fig. 1). Suprapubic catheterization was performed and she was put on tidal drainage. After three weeks the right kidney was secreting, the left being still dilated. At this time a cystogram (fig. 2) showed a conical bladder with a reflux up a dilated and tortuous right ureter into a dilated renal pelvis. After nine months she was able to pass all fluid from her bladder except 1¼ oz.: the suprapubic catheter was removed, the fistula never leaked and was closed in a day. After closure the intravenous pyelogram showed good function on both sides with only a little dilatation on the right (fig. 3). When seen after a year the pyelogram was unchanged, the urine was clear, and she was able to empty her bladder and was not incontinent. The duration of suprapubic drainage in this case was nine months, and no fixed time limit can be laid down. *(See illustrations next page.)*

It is our aim at present to close the bladder in all cauda equina lesions when it can be done with safety, and we are closing more of those with cord lesions than formerly. In these the patient must wear a urinal, but the psychological effect of a closed bladder is very great. The safety factors are a satisfactory general condition, a small residual urine (probably not more than 2 oz.) and relatively little infection. When the fistula has been closed any slight vesical infection will often clear up provided there is not much residual urine.

In a conus lesion in a girl of 20 with permanent paralysis a small suprapubic catheter was retained for two years. On its removal the fistula was dry in two days and she regained a continent bladder, emptying by straining with less than 2 oz. of residual urine and no infection. She can sleep through the night without passing urine and goes for four hours by day.

Closure of the small high fistula after suprapubic catheterization is rapid and spontaneous; closure of a fistula after a low cystotomy is prolonged and it usually needs excision. Most of the cases admitted to the Centre have already got a suprapubic cystotomy done by the older methods and the fistula is often adherent to the symphysis. These tax the surgeon's resources considerably when the time comes for their closure. Thus there has been little opportunity for the use of serum needle inserted well above the pubes. This may if necessary be repeated once, but frequent aspiration is likely to lead to extravasation. Under peacetime conditions however it should rarely be impossible to get the patient into hospital within twenty-four hours; during the war mobile teams often made surgical treatment available in a shorter time.

Let us then assume that twenty-four hours have elapsed, the bladder is distended, there has been no voluntary or automatic micturition and the surroundings are such that reasonable asepsis is possible. Is the bladder to be drained by urethral or suprapubic catheter? I may say at once that I strongly advocate the suprapubic route for general use. It is true that we have had one or two cases received into the Spinal Injuries Centre at Stoke Mandeville very soon after their injury where the urethral catheter combined with tidal drainage and adjuvant measures have been used successfully, but they form a very small minority. They require infinite care and unlimited time, and their supervision is a one-man job. Incidentally paraplegics should never be catheterized by an orderly. When drainage is established it must be adequate and regular or continuous; it must be such as to prevent extreme contraction or excessive dilatation of the bladder, there must be no urinary leakage, and above all it must avoid the possibility of serious infection. The method must be one which the nursing staff can understand and care for. The method I advocate is the introduction of a small suprapubic catheter into the upper part of the distended bladder. Its track must be oblique, and the catheter must fit closely. I do not refer to suprapubic cystotomy as usually performed. We all have often been horrified by the large tube placed at the bottom of a long incision with urine leaking around it and infection getting in. At a later stage the track becomes adherent to the pubes and closure is at best delayed and at worst impossible. Moreover the bladder is allowed to contract down to a small capacity. and any periodic reflex micturition which may ultimately develop is useless because of its frequency. Examples have been shown previously (Riches, 1944).

I have described elsewhere the method of suprapubic catheterization (Riches, 1943*a*, *b*); the small catheter, size 16F, is inserted into the distended bladder through a small incision in the abdominal wall. Its point of entry is opposite the highest point of bladder dullness or the mid-point between the umbilicus and the symphysis, whichever is the lower. Its direction is obliquely downwards and backwards. It is rapid, requires no great technical skill but only a modicum of common sense, and is quite safe provided that the bladder is distended. If this is not the case the bladder must be exposed through a short incision before the catheter is introduced. The catheter must be changed after fourteen days and subsequently once a week. Any straight rubber catheter of the same size can be used and no introducer is required, the only necessity being asepsis. If the catheter is to be retained for many weeks it is replaced by one a little larger, size 20F being usually adopted.

Cases treated by this method have proved satisfactory, and it would appear that the principle of suprapubic drainage is not at fault.

TIDAL DRAINAGE

When drainage has been established it must be continuous; any obstruction of the catheter will make it act as a cork and will be followed by signs of infection. This applies particularly to cases previously infected by urethral catheterization. The best way of ensuring continuity is by efficient tidal drainage. The apparatus we use, the "double Y", is convenient because it incorporates a cystometer. An irrigating fluid designed to keep the urine acid is preferable. Where there is a tendency to phosphatic deposition the solution G of Suby (1942) is of most value.

The value of tidal drainage has been questioned by those who maintain that small doses of sulphonamides are more effective in preventing infection. Unfortunately sulphonamides cannot be continued indefinitely whilst tidal drainage can. To me one of the most encouraging facts about it is that of the few men discharged with permanent suprapubic tubes most continue to keep their tidal drainage going every night.

It is often asked why suprapubic drainage gives less liability to serious infection than urethral drainage. It may be stated at once that suprapubic drainage does not prevent infection of the bladder; whenever a tube is passed into the bladder and retained there infection is bound to gain entrance in time. With a catheter in the urethra, however, there is always urethritis and it has been shown that the path of ascending infection is by direct lymphatic spread from the deep urethra by peri-ureteral lymphatics to the kidneys. There is no such direct lymphatic connexion from the track of a suprapubic catheter to the kidneys, and ascending infection is much less common from a bladder which is draining freely. Infection of the bladder is not lethal but infection of the kidneys is.

The effect of inadequate drainage.—The policy of absolute non-interference with the bladder has been advocated from time to time, the bladder being left alone until the stage of retention with overflow is followed by automatic micturition. This certainly obviates the risk of instrumental infection but it does carry the dangers of prolonged overdistension. The time before periodic reflex micturition is established is uncertain and may be more than a year in cauda equina lesions and serious renal damage may ensue if the bladder is not drained. Perhaps the worst danger lies in irregular intermittent catheterization which leads to infection without securing continuous drainage.

A woman of 25 developed a cauda equina lesion following a spinal anæsthetic. She was catheterized occasionally but allowed to go home with urinary incontinence, before periodic reflex micturition was established. I saw her six months later when she had a distended bladder with overflow incontinence and gross urinary infection. The right kidney was hardly secreting, the left was dilated, and the bladder held 17 oz. (fig. 1). Suprapubic catheterization was performed and she was put on tidal drainage. After three weeks the right kidney was secreting, the left being still dilated. At this time a cystogram (fig. 2) showed a conical bladder with a reflux up a dilated and tortuous right ureter into a dilated renal pelvis. After nine months she was able to pass all fluid from her bladder except 1¼ oz.; the suprapubic catheter was removed, the fistula never leaked and was closed in a day. After closure the intravenous pyelogram showed good function on both sides with only a little dilatation on the right (fig. 3). When seen after a year the pyelogram was unchanged, the urine was clear, and she was able to empty her bladder and was not incontinent. The duration of suprapubic drainage in this case was nine months, and no fixed time limit can be laid down. *(See illustrations next page.)*

It is our aim at present to close the bladder in all cauda equina lesions when it can be done with safety, and we are closing more of those with cord lesions than formerly. In these the patient must wear a urinal, but the psychological effect of a closed bladder is very great. The safety factors are a satisfactory general condition, a small residual urine (probably not more than 2 oz.) and relatively little infection. When the fistula has been closed any slight vesical infection will often clear up provided there is not much residual urine.

In a conus lesion in a girl of 20 with permanent paralysis a small suprapubic catheter was retained for two years. On its removal the fistula was dry in two days and she regained a continent bladder, emptying by straining with less than 2 oz. of residual urine and no infection. She can sleep through the night without passing urine and goes for four hours by day.

Closure of the small high fistula after suprapubic catheterization is rapid and spontaneous; closure of a fistula after a low cystotomy is prolonged and it usually needs excision. Most of the cases admitted to the Centre have already got a suprapubic cystotomy done by the older methods and the fistula is often adherent to the symphysis. These tax the surgeon's resources considerably when the time comes for their closure. Thus there has been little opportunity for the use of suprapubic catheterization in the war cases, but I have used it in other paraplegics and have found it trustworthy.

Even with formal suprapubic cystotomy which has been extensively used during the latter part of the war the results have been incomparably better than they were when urethral catheterization was the rule, and the results we are getting now are a great advance on those I saw in the Spinal Injuries Centres in 1942. I am sure they can be improved still further by the adoption of the small high suprapubic catheter in place of the large low cystotomy tube for both the initial and subsequent treatment of the bladder until automatic action is established.

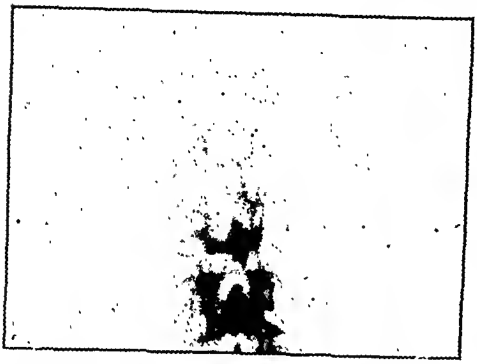

FIG. 1.—Cauda equina lesion without drainage. Excretion urogram (45 min. film). No secretion on right, hydronephrosis on left.

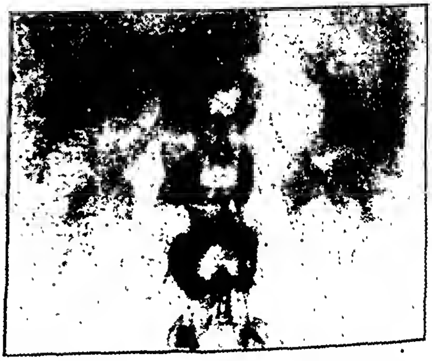

FIG. 3.—Same case nine months after suprapubic catheterization (15 min. film). The bladder is now closed.

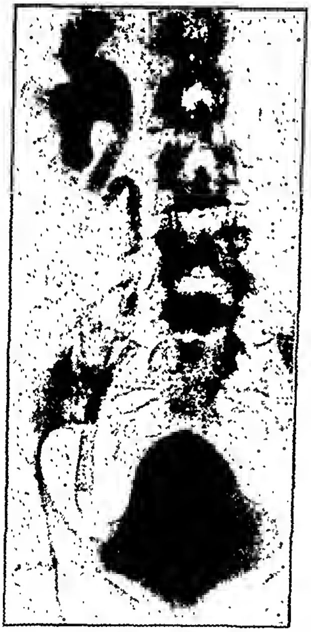

FIG. 2.—Same case; cystogram showing right ureteric reflux.

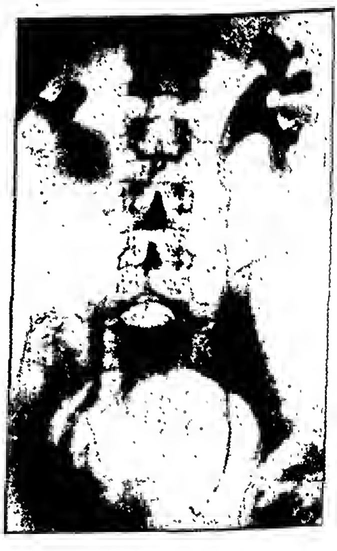

FIG. 4.—Cauda equina lesion treated by urethral catheterization. Pyelogram showing bilateral hydronephrosis and hydro-ureter.

I have already mentioned that one or two cases treated by urethral catheterization at the Centre from the outset have obtained excellent results, but I still feel it is not a method for general use. A cauda equina lesion (fig. 4) was treated elsewhere by urethral catheter; he is clinically well and has a good automatic bladder, but his urine is infected and pyelography shows both kidneys to be dilated, a poor augury for his future.

Stone formation.—Infection, recumbency and dilatation of the upper urinary tract are potent factors in producing renal calculi, and the stones formed in these cases are generally hard, and extensive. Although they are phosphatic they show little tendency to disappear when the patient is able to be up and about, and they must be removed surgically. Stones in the bladder can sometimes be dissolved by the use of solution G in the suprapubic tidal drain.

After removing renal stones it is an advantage to leave in a nephrostomy tube for several weeks so that daily lavage with solution G can be carried out, but I have had no success in dissolving formed renal calculi by this method.

Dr. D. Whitteridge: *Physiological disturbances produced by distension of the bladder.*—Clinically, the most conspicuous feature of the disturbances produced by distension of the bladder in patients with high spinal lesions was the flushing of the face and neck. A conventional multiple-junction skin thermometer was made up, and used for the recording of the temperature in the feet, rectum, trunk and neck. The rectal temperature was found to rise slightly, that of the neck rose two to three degrees, while that of the feet fell sharply. A redistribution of blood on a considerable scale therefore seemed to be taking place, and arrangements were made to record at short intervals blood-pressure and pulse-rate in addition to the skin temperature. The usual difficulties in the interpretation of skin temperature changes led us to follow the peripheral blood flow plethysmographically, and a transportable apparatus was constructed for the photographic recording of pulse volumes and finger blood flow (by the method of Wilkins, Doupe and Newman, 1937), bladder pressure, ear volume and blood-pressure. The method of Evans and Mendelssohn (1946) was adapted by Mr. R. W. Gilliatt for photographic recording.

When the bladder was filled slowly, there was a profound finger and toe constriction, accompanied by a rise in blood-pressure, as soon as active contractions of the detrusor muscle began. In patients with lesions above T. 5, the rise in systolic pressure was 70 to 160 mm.Hg, and the diastolic rise was 50 to 90 mm.Hg. There was a sharp initial fall in the pulse-rate, which later rose towards normal while the bladder distension continued. The volume of the pulse in the ear rose, as did its temperature, even in a patient with a complete lesion at C. 8.

In patients with lesions at or below T. 6, the picture was rather different. There was the same fall in temperature of the legs, and profound fall in the pulse volume in the toes, with even greater falls in the pulse-rate, but the blood-pressure did not rise more than 30 mm.Hg, and the blood flow in the fingers increased.

When the bladder was suddenly distended with 60 c.c. of water at body temperature, vasoconstriction began in five to six seconds, and was followed almost immediately by a rise in blood-pressure.

It would seem that the essential difference between the two groups of patients is that in those with the lower lesions vasomotor regulation is still possible, since there are still large areas of the vascular bed which can be used by the vasomotor centre for compensatory vasodilatation. With lesions above T. 5, the area controlled by the vasomotor centre is greatly reduced, and with lesions above T. 1, the only efferent path from the vasomotor centre is formed by the cardio-inhibitory fibres of the vagus. To make matters worse, the cardio-accelerator fibres which arise from the isolated cord are probably being excited.

Distension of the rectum by a balloon caused a similar rise in blood-pressure, with vasoconstriction, sweating and pilomotor activity in the arms. These effects were rather transient, while those elicited by distension of the bladder persisted as long as distension was maintained. Distension of parts of the alimentary tract has already been shown to produce vasoconstriction in the toe, and, to a lesser extent, in the finger (Carmichael, Doupe, Harper and McSwiney, 1939). From their evidence, it is likely that the vasoconstriction which they observed is due to a reflex rather than to a central phenomenon related to pain. There can be no question that our phenomenon is due to a spinal reflex, and it seems likely that distension of some hollow viscera can give rise to a peripheral vasoconstriction, which, in these patients, can spread to involve the whole of the sympathetic vasomotor outflow of the isolated cord.

Dr. P. H. A. Jonason: The rehabilitation of high lesions is found difficult owing to vasomotor disturbances.

That cerebral anæmia due to postural changes causes fainting attacks in convalescent patients following any illness which entails a long rest in bed is well known.

However, very little has been published about details of the effects of changes of posture on the vasomotor system of spinal man.

Experimental work on animals on this subject was initiated in this country by Leonard Hill and Barnard in 1897. It seemed worth while studying this problem on a number of paraplegics at various levels, the more so as some of the patients showed more difficulty in adapting themselves to the upright position than others. It was found that whilst spinal cases with more distal cord lesions did not differ from other non-spinal convalescent cases in their vasomotor reactions those with high thoracic and cervical cord lesions showed more profound and longer lasting effects to postural changes. In this short report details are given only of our findings on the pulse-rate, diastolic and systolic blood-pressures and subjective sensations noticed by the patient.

Method.—In order to produce maximal effects a tilting table was used. The apparatus consisted of a standard army stretcher fitted to a frame enabling the stretcher with the patient on it to be rapidly tilted from the horizontal position to the vertical feet-down position. The patient lies on a sorbo rubber mattress and is comfortably secured. Great care was taken to avoid any undue pressure which might obstruct even superficial blood circulation and respiratory movement; the head, neck, arms and upper trunk being completely free. All cases with indwelling suprapubic catheters were fitted with bottles to allow an unobstructed bladder drainage and so avoid the converse effects of a distended viscus below the level of the lesion.

Repeated recordings of the pulse-rate and the blood-pressure were then taken until three consecutive recordings at one-minute intervals showed a constant pulse-rate and blood-pressure.

These recordings were taken by independent observers, both taking part in observing changes in the patients themselves. The patients co-operated extremely well in stating effects that they themselves noticed such as dimness of vision, tinnitus and feelings of faintness.

Once the blood-pressure and pulse-rate were stabilized the table was tilted from the horizontal position to the vertical feet-down position. This alteration of position took only one and a half seconds and immediate recordings were taken at one-minute intervals until either the patient complained of unpleasant feelings, or showed signs of syncope or twenty minutes had elapsed. At the end of this time, the table was again returned to the horizontal position and recordings repeated until the blood-pressure and pulse-rate had returned to normal or all side-effects had passed off.

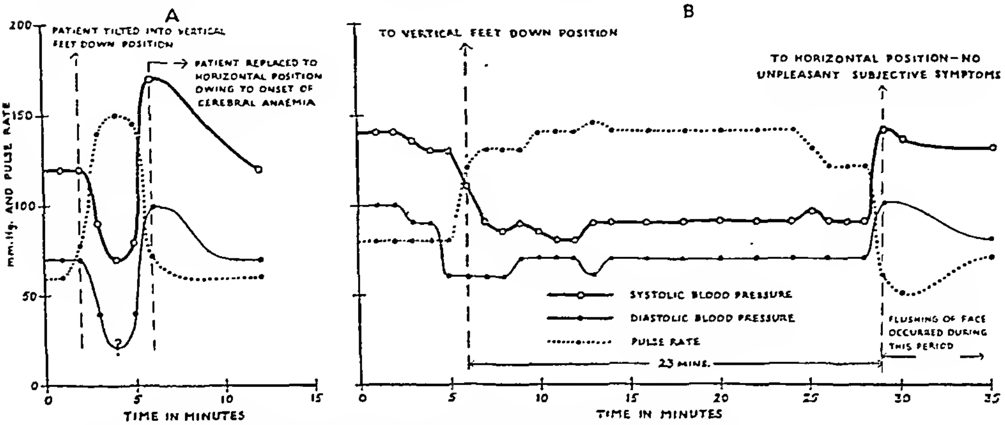

CHART I.—Patient H. H., aged 24. Transverse spinal syndrome at T. 4.

Experiment A was carried out on 30.5.46 and lasted only four minutes in the vertical feet-down position before cerebral anæmia set in.

Experiment B was carried out on 18.9.46 and no ill effects occurred even after maintaining the vertical feet-down position for twenty-three minutes.

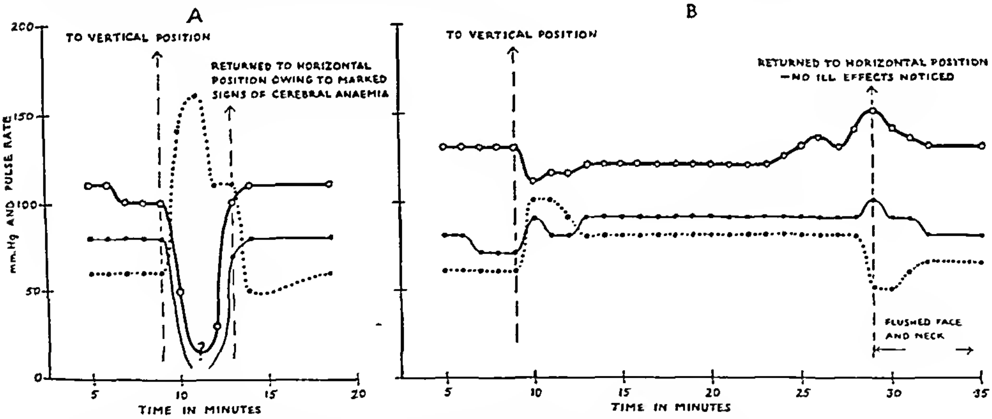

CHART II.—Patient A. H., aged 23. Complete transverse spinal syndrome at T. 3.

Experiment A was started on 30.8.46 and lasted only four minutes, owing to profound cerebral anæmia causing unpleasant subjective symptoms.

Experiment B on 29.10.46. There were no ill effects after twenty minutes, the systolic blood-pressure actually increasing.

Dr. W. Ritchie Russell: In the care and rehabilitation of traumatic paraplegia neither the neurologist nor the orthopædic surgeon is able to deal properly with these cases with the facilities usually at their disposal, and it is clear that the argument for their segregation in special Centres is indisputable. It is only in the special Centre that the sometimes conflicting interests of the care of the fractured centre for compensatory vasodilatation. With lesions above T. 5, the area controlled by the vasomotor centre is greatly reduced, and with lesions above T. 1, the only efferent path from the vasomotor centre is formed by the cardio-inhibitory fibres of the vagus. To make matters worse, the cardio-accelerator fibres which arise from the isolated cord are probably being excited.

Distension of the rectum by a balloon caused a similar rise in blood-pressure, with vasoconstriction, sweating and pilomotor activity in the arms. These effects were rather transient, while those elicited by distension of the bladder persisted as long as distension was maintained. Protrusion of Intervertebral Discs

By R. H. YOUNG, F.R.C.S.

THIS is an Address which B. H. Burns and I prepared before the International Orthopædic Congress held on October 3, 1946, and which he delivered in Brussels.

Burns and I have had the opportunity at a war hospital, of dealing with a considerable number of patients with sciatica and backache.

Those who have been reluctant to accept that operation is a cure for sciatica, have the habit of remarking "what used to happen to these cases before their discs were removed? Nearly all of them got better" they would say.

We have the records of many cases of sciatica which were treated by all the methods then in vogue in the years before we operated. 248 of them were available for follow-up last year.

PATIENTS WITH SCIATICA

		Still in pain or having attacks %	Symptomless %	Total
Not operated on				
First seen 1939-42. Followed up 1945		79	21	248
Operated on				
1941-45 Followed up 1946	Improved 11% No better 9%	20	80	310

Since 1942 all but 9 patients with severe sciatica have been operated on.

The table shows that 4 out of 5 were still having attacks; also, that since we began operating on them in 1941 the position is reversed, 80% are now symptomless and 20% still have some pain.

All but 9 cases of severe sciatica have been operated on.

The conditions found at laminectomy have been as follows:

CONDITIONS FOUND AT LAMINECTOMY FOR SCIATICA AND BACKACHE

Disc lesions	470
Spondylolisthesis	20
Root irritation from osteo-arthritic lip	11
Root irritation from narrowed foramen	6
Cauda equina tumour	1
Abscess from osteomyelitis	1
Unknown	24
TOTAL	533

Since we have operated on nearly every severe case of sciatica it follows that protrusion of a disc is by far the commonest cause of sciatica. A bad second is spondylolisthesis.

Also we consider that a disc lesion is the commonest cause of recurrent backache, but the proof of this is not quite so definite as we have not checked our diagnosis by operation so often. Nevertheless we have operated on 45 patients with backache only and we found, in all but 2 of these, a lesion of a disc. The reason why this number is relatively small is that those patients with backache alone are seldom bad enough to require operation. They tend to get better, or if they get worse they develop sciatica. Further the majority of patients with sciatica due to protrusion of a disc, have, in their early stages, signs and symptoms of backache only.

EARLIEST SYMPTOMS IN 470 PROVED DISC LESIONS

Backache	68%
Sciatica	24%
Backache and sciatica	8%

bones of the spine, the anæsthetic skin, and the patient's morale are likely to be properly balanced.

Dr. P. W. Nathan asked Mr. Riches whether, if an automatic bladder is obtained within a few weeks or even a few months, it would not be preferable to close the suprapubic cystotomy, and continue treatment with tidal drainage, manual expression and intermittent catheterization, combined with sulphadiazine. Such a line of treatment seems possible now that there is such effective therapy in the form of sulphadiazine and the newer sulpha drugs. During the campaign in Italy he found that when sulphadiazine was given to cases with suprapubic cystotomies, the urine could be kept sterile; it remained free from *B. coli*, and microscopically contained less than 10 leucocytes per field.

Dr. Giles Romanes: I have treated one case of bladder stones in a paraplegic patient with solution G on two occasions. It was able to dissolve a phosphatic calculus which was approximately the size of a marble in ten days. Three days later an X-ray proved that the stone was absent. In my experience the saving of time of four weeks in the dissolution of a stone is entirely due to the method of administering the solution G. I used a double suprapubic catheter so that the solution G was poured directly on to the stone. The catheter is made by taking a No. 34 de Pezzer and cutting an oblique nick in the wall about 2½ in. from the peripheral end. The hole made is valvular and a fine prostatic soft rubber catheter is inserted down the lumen of the de Pezzer projecting 2 in. through the proximal end. This allows for the stretching of the whole over the introducer. The external junction between the catheters is sealed off with ordinary puncture-mending rubber solution. This method completely eliminates any dilution of the active agent with urine as is bound to happen when it is administered by means of a tidal apparatus.

Mr. Riches, in reply to Dr. Nathan, stated that the bladder must be drained because it is paralysed. He did not wish to drain it for as long as two years but the period before recovery was uncertain and it was better to maintain drainage until the maximum recovery was obtained as shown by cystometry, power of emptying and lack of residual urine. He agreed that urethral drainage would give earlier recovery than suprapubic drainage if it could be kept free from infection, but experience in its general use showed that it could not.

He agreed that solution G must come into constant and intimate contact with stones if it was to be effective.

The President: We began the second World War with a much better knowledge of traumatic paraplegia as a result of the classical work of Head and Riddoch. However, the ultimate outlook for these patients seemed no brighter than it had been following the first World War until the Peripheral Nerve Injuries Committee, with Dr. George Riddoch as chairman, recommended setting up Spinal Injuries Centres in this country, of which that run by the Ministry of Pensions at Stoke Mandeville Hospital became the best known. Dr. Guttmann has shown us that not only has the expectation of life of these patients been materially improved, but that with appropriate methods of treatment and rehabilitation, a degree of functional recovery may be achieved that a few years ago would not have seemed possible. This discussion has shown that the successful treatment of the paraplegic bladder depends, as a rule, not so much on the method used as on the skill of the personnel who carry out the treatment. Mr. Riches has made a strong case for high suprapubic catheterization as a routine measure in these cases. Whatever method is adopted it is clear that a urologist should co-operate in the treatment of these cases from the beginning.

PATHOLOGY

At operation we have found that there are two kinds of protrusion. One is a protrusion of the nucleus pulposus and the other is a tear of the annulus fibrosus. In a nuclear protrusion the annulus is intact and the nucleus comes out between the top or bottom of the annulus and the vertebral body. Fig. 1 illustrates the nuclear protrusion.

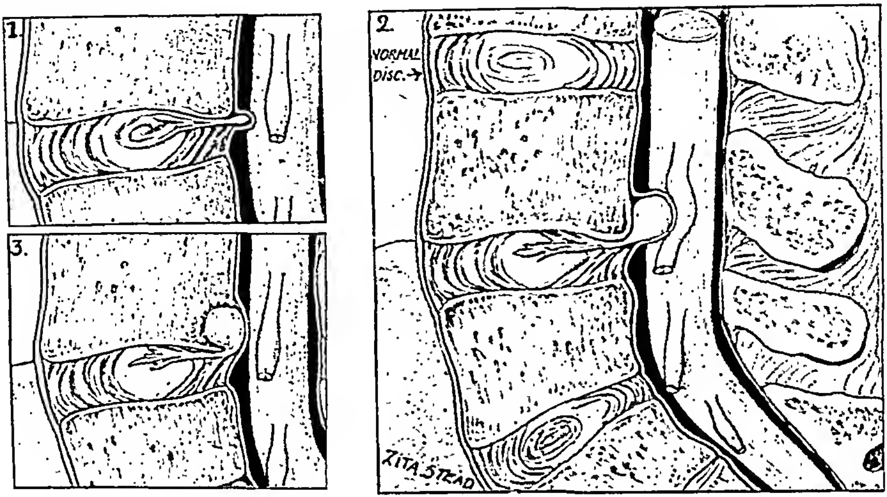

FIG. 1.

1.—Small protrusion. At this stage it can pop in and out. We have pushed them back at operation. When reduced it will be missed. Therefore one should operate only during an attack. 2.—Larger protrusion. This causes pressure on nerve and sciatica. 3.—A later stage of 2. The protrusion has eroded the vertebral body—the pressure on the nerve root is therefore released—the sciatica is relieved, but the patient is left with a lame back. This lesion has sometimes been found in patients with a "lame back" following a prolonged attack of acute sciatica which has gradually cleared up.

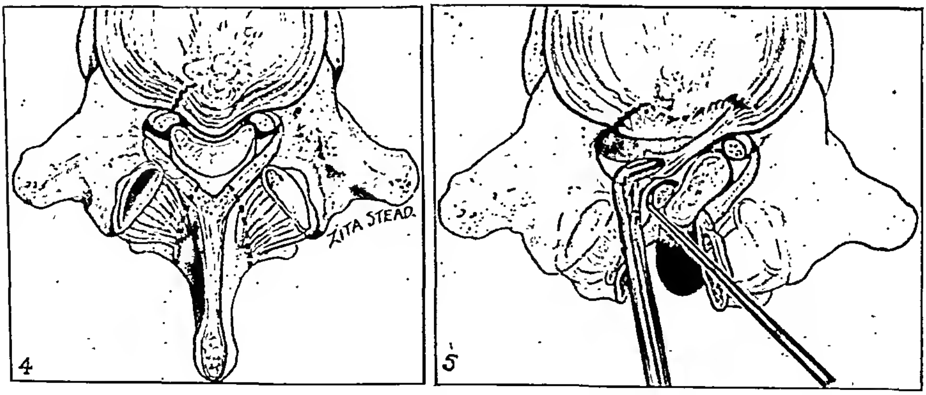

FIG. 2.

Fig. 2 illustrates an annular tear. The whole thickness of the annulus is torn. It mimics a torn meniscus, and swings in and out. It is not only necessary to remove the piece of torn annulus, but all the nucleus must be removed as well, like removing the charge from a shell. Not doing so was the cause of some of our early failures. In our opinion it is not necessary, like Dandy, to remove the whole disc—all of the annulus—in an attempt to get ankylosis.

The pain may be in the back alone for months and even years before the sciatica develops. Our general views on backache and its causes are as follows:

(1) Chronic or recurrent low backache without physical signs = visceral lesions or neurosis.

(2) Chronic or recurrent low backache with physical signs = disc lesion unless X-ray shows other conditions, such as spondylolisthesis or spondylitis.

Diagnosis.—A disc lesion may be suspected from the history. In fact, a diagnosis can often be made over the telephone from a story of recurrent attacks of backache and stiffness. Suspicions are confirmed if there are back signs as well. These are restriction of forward bending whilst sideways bending is free. The diagnosis, so long as the X-ray is negative, can be made on this sign alone.

(1) In sciatic scoliosis lateral bending is free to the side which increases the deformity.

(2) Sciatic scoliosis is always due to a disc lesion.

Neurological signs are only of value as confirmation. 40% of patients operated on by us have had none. Surgeons by insisting on their presence before a positive diagnosis of a disc protrusion is made are apt, by their delay, to prolong the patient's suffering unnecessarily.

We only operate on about half the patients we diagnose as having a disc lesion. In a first attack, the patient is put to bed for three weeks and if the pain persists an operation is recommended. Our threshold for operation is lower than it used to be, and we feel justified in this from the fact that none of our 533 laminectomies have been made worse. The operation is without danger, although it is not without difficulty.

If it is decided to operate it would be a help to know which disc is at fault, but although we know that 95% occur at the lowest two discs, it is impossible to localize the lesion to either of these two. It has often been claimed that localization is possible by neurological signs, but the following table shows that this is not so.

FREQUENCY OF MAIN NEUROLOGICAL SIGNS IN PROVED DISC LESIONS
With neurological signs, 61%; without neurological signs, 39%

	Ankle-jerk		
	Normal	Diminished	Absent
5/1 disc ..	39	24	37
4/5 disc ..	67	20	13
3/4 disc ..	2 cases—normal		

	Sensation	
	Normal	Diminished outer border of foot
5/1 disc ..	58	39
4/5 disc ..	70	27
3/4 disc ..	2 cases—normal	

3% have diminished sensation inner border of foot.

Thus neurological signs are useless for localization. 39% of the patients have no neurological signs, and, of the main neurological signs, changes in the ankle-jerk and changes in sensation can be present in a similar proportion in both 4/5 and 5/1 disc.

Further we have had no help from myelography either with opaque media or with air. We consider that the procedure is misleading and if lipiodol is used, dangerous, as it leads to arachnoiditis.

Therefore, we remove the whole of the fifth lamina and adjacent ligamenta flava, so as to have free access to both of the lower two spaces. We have not found that this led to a weakened back.

We operate with the patient lying on his side. This has many advantages:

(*a*) It is the easiest way to flex the spine (Pridie has him like a rabbit about to take off). (*b*) The blood runs away from the bottom of the wound. (*c*) The patient is much less shocked than when lying on his face with pressure on the solar plexus.

Incidentally, it is much more comfortable as operators can sit and onlookers can see more easily.

attempt to solve it by using a parallel nail and graft, the technique of which was simplified by Wardle's ingenious and simple modification of a trifin nail.

Comparison with Wardle.—The method, although not so simple as that used by Wardle, is far more effective in that it prevents the nail from cutting out anteriorly through the head of the femur as a result of external rotation of the leg.

It has, in fact, been used as a second operation where a Wardle nail and graft had failed and in this instance held very securely, in spite of the fact that the head had a groove ploughed in it, the breadth of the original nail and graft.

Method.—The trifin nail is introduced by any method with which the surgeon is familiar, but care should be taken that the nail is as vertical as possible and in the centre of the head in the A.P. view and well posterior in the lateral view (fig. 1).

A graft is cut from the opposite tibia, four inches long and half an inch broad, whilst the first X-rays are being developed. Then after a satisfactory position has been obtained for the nail, an opening is made for the graft to be inserted, half an inch above the nail and in front of it, on the lateral femoral cortex just below the greater trochanter. Through this opening which is made with a gouge, a half-inch osteotome is driven in so as to make a path for the graft, which must converge on the line of the nail and pass anterior to it (fig. 2).

This may seem somewhat complicated, but actually with the line of the nail as a guide, it is not as difficult as it sounds. The osteotome is driven in for an estimated distance, depending on the measurements obtained from the X-ray, but in practice fairly consistently 9 cm., and then an X-ray is taken. If this proves satisfactory, in both A.P. and lateral views (figs. 3 and 4) the osteotome is withdrawn and the graft substituted for it.

If it is not satisfactory, necessary adjustments in the alignment of the osteotome are made until a satisfactory position is obtained.

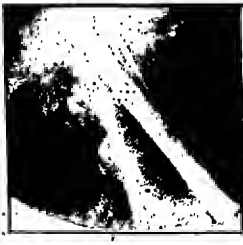

FIG. 1.

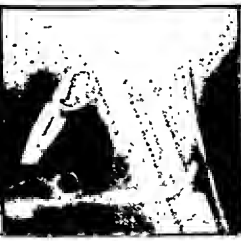

FIG. 2.

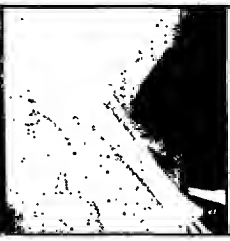

FIG. 3.

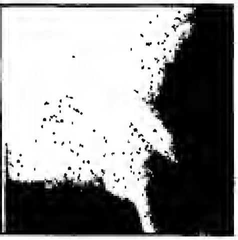

FIG. 4.

FIG. 1.—Ideal position in the A.P. view. The nail will be driven farther in before the operation is completed.

FIG. 2.—Lateral view showing the trifin nail posterior and the osteotome cutting the path for the graft anterior, in the neck of the femur.

FIG. 3.—A.P. view showing graft crossing the line of the trifin nail.

FIG. 4.—Final position, nail driven well in and graft ending in the lower quadrant of the femoral head.

Advantages.—The chief advantage which is obtained by this crossing is that it prevents the nail from breaking out anteriorly, as it has not only to cut a pathway for itself through the head but also has to force the graft to travel in front of it, through a separate portion of the head. In fact the resistance of the graft is sufficient to cause it to fracture before it can be forced to give way.

This must be contrasted with the state which exists when the graft and nail are

In the first table we stated that 9% of our cases were no better and 11% were still having some trouble. We have sought to explain these failures and have concluded that they fall under five causes.

POSSIBLE CAUSES OF FAILURE IN PROVED DISC LESIONS AND TREATMENT RECOMMENDED

Cause	Treatment	Comment
(1) Protrusion of another disc	Re-exploration with removal of protrusion	(1) In 8% of our cases there were two protruded discs. Failure to recognize the second protrusion is a cause of failure
(2) Incomplete removal of nucleus pulposus		(2) Already discussed (*see* p. 11)
(3) Adherent nerve root becoming persistently re-attached	Re-exploration and graft	(3) In old-standing cases with dense adhesions the nerve root may become stuck again
(4) Mechanical arthritis of intervertebral joint ..		(4) Sometimes accompanies a diminished intervertebral space
(5) Diminished joint-space with narrowing of foramen and root compression ..	Facetectomy	(5) Putti's lesion. We do not often find it.

Thus, from our experience, practically all cases of sciatica and most cases of backache can be cured by operation. There is no alternative except rest and that is shown to be much less effective than operation.

Summary.—(1) Almost all sciatica and recurrent backache is due to disc lesions.

(2) The diagnosis can be made on back signs alone.

(3) Only operation offers the patient a definite prospect of cure.

The Crossed Trifin Nail and Graft in the Treatment of Fractures of the Neck of the Femur

By G. K. McKEE, F.R.C.S.

THE simple insertion of a trifin nail in fractures of the neck of the femur, although considered the best initial method of fixation for these fractures, leaves much to be desired as far as end-results are concerned. There are *two main complications* which are responsible for this:

One is *aseptic necrosis* which is a not infrequent cause of failure some months later.

The other is the cutting out of the nail which is an earlier complication than aseptic necrosis and usually occurs a few days or weeks after the operation in spite of the nail being well placed. Even with firm impaction of the fragments and careful after-treatment the nail may not hold and displacement with consequent non-union occurs. Non-union when occurring in old people is a real problem. The two complications of aseptic necrosis and cutting out of the nail are sometimes associated, the nail cutting out because of the degeneration of the head of the femur.

The cutting out of the nail.—This paper is concerned with the cutting out of the nail anteriorly and the introduction of a method of nailing and grafting these fractures which is designed to prevent it.

The problem is not a new one and various contributions have been made in an present series. An example of a successful osteotomy is shown in figs. 1 and 2 (Patient E. H.). In this case the late result is shown after ten years and the lower fragment has grown away from the pelvis. Reossification across the diseased joint after displacement osteotomy may occur for three reasons: First, shearing strains are prevented by osteotomy; secondly, ossification is favoured in ischæmic tissue, and ischæmia may be promoted in the femoral head and neck by division of vessels running in the upper end of the femoral shaft; thirdly, as I have attempted to show in a previous paper (*Proc. R. Soc. Med.*, 1946, **39**, 712), the theory of Lavalle and McCrae Aitken may apply and incision of tuberculous bone may of itself be of benefit. I have frequently performed these osteotomies through tuberculous bone or through a tuberculous abscess. So far from harm having been done, considerable improvement has resulted.

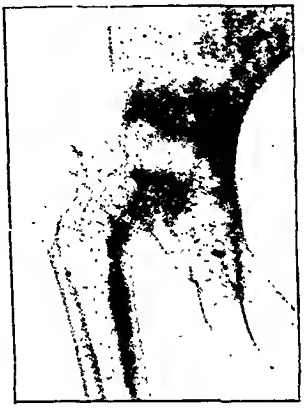

FIG. 1.

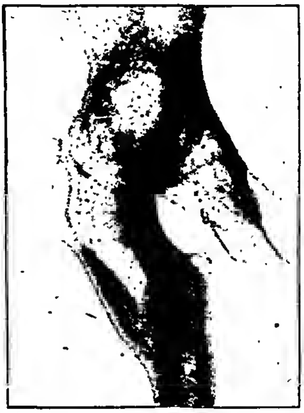

FIG. 2.

E. H., female. FIG. 1.—Tuberculous hip with unsound ankylosis treated by displacement osteotomy. FIG. 2.—Same hip on late follow-up.

Table I shows the result of displacement osteotomy in 21 patients whose hip disease had become quiescent, but in the majority of whom there had developed some deformity or reactivation of disease. Three of these cases were complicated by the presence of chronic discharging sinuses which had not responded to conservative treatment. There was no delay in bone union following osteotomy, and the hips subsequently became stable with healing of the sinuses.

TABLE I.—DISPLACEMENT OSTEOTOMIES WITHOUT GRAFT IN 21 PATIENTS: OPERATIONS TWO OR MORE YEARS AGO: APPARATUS DISCARDED

Firm ankylosis: stable hip	21 cases
Bone ankylosis (13 cases)	Fibrous ankylosis (8 cases)
Children 9, Adults 4	Children 4, Adults 4

In a second series of patients a bone graft was used to augment the displacement osteotomy. An example of this type of osteotomy and graft is shown in figs. 3, 4, 5 (Patient A. H.). I first used the graft as an additional source of osteogenetic tissue, having in mind Lavalle's observation that the results of his operation were better if sliver grafts were inserted into tuberculous bone. The operative method is as follows: An incision is made along the outer and upper aspect of the femoral shaft, and at the tip of the great trochanter it is tailed obliquely backwards in the line of the fibres of the gluteus maximus. In the lower part of the wound the incision is then carried down to the femoral shaft. In the upper part of the wound the gluteal fibres are splinted and retracted. A graft is then cut from the upper end of the parallel with the graft lying anteriorly, for then the nail and graft can travel through the same pathway in the head.

Disadvantages.—The operation time is lengthened when compared with the simple insertion of a nail and a more extensive exposure of the lateral femoral cortex is required.

The post-operative shock is therefore liable to be greater than in the simple insertion of the nail.

For very old and feeble patients this method is best avoided, but if the patient has been up and about prior to the accident and has no added nervous cardiac or pulmonary complications, then it is to be preferred.

The actual cutting of the graft need not add to the length of the operation, as it can be arranged to be done while awaiting the X-rays. Good and quick X-ray technique in the theatre is essential.

Results.—In the course of the last three years I have treated 17 cases by this method and there has been only one failure and this was in a case of a pathological fracture, an osteoclastoma, where there was a rapid bone erosion after the operation. It should not strictly be included in the series.

Intertrochanteric Osteotomy for the Treatment of Tuberculosis of the Hip

By M. C. WILKINSON, M.B.

CONSIDERATION is given in this paper to any oblique osteotomy which achieves the inward displacement of the upper end of the lower fragment of the femur against the under surface of the acetabulum. Such an osteotomy is often intertrochanteric but may be subtrochanteric if there has been much destruction of the acetabular roof by the disease. The chief difficulty of the operation is to produce adequate inward displacement of the lower fragment. This is essential for success. When the bifurcation osteotomy was popular, inward displacement of the lower fragment was effected by placing the limb in marked abduction. In most cases I have avoided this because a fixed abduction deformity may be a crippling condition. Mr. S. L. Higgs has said that an oblique osteotomy should be either above or below the small trochanter, because osteotomy into the psoas tendon makes displacement of the lower fragment very difficult. The osteotomy should be done under X-ray control. By means of a successful osteotomy of this type, stabilization of the hip may frequently be achieved.

Constitutional treatment is essential for tuberculous disease of the hip. Yet an unstable hip is often the result of conservative treatment only, and a proportion of the patients develop reactivation of the disease or deformity. In a series of 50 cases of tuberculosis of the hip treated conservatively which I followed up in 1938, 22 had an unstable hip at the end of treatment. Of these 22 cases, 6 had later to be readmitted for the treatment of fresh disease and 7 for the treatment of deformity. A displacement osteotomy performed when the disease was becoming quiescent might have produced stability of the hip in some of these children. Sir Henry Gauvain used to say that stability followed the bifurcation operation, but insisted that the patient should wear a well-moulded celluloid splint for a sufficient time afterwards. The word stability is used in its clinical sense and means that deformity does not occur and the disease does not reappear after apparatus has been discarded. Bone ankylosis is not necessarily present, but occurred in the majority of cases in the present series. An example of a successful osteotomy is shown in figs. 1 and 2 (Patient E. H.). In this case the late result is shown after ten years and the lower fragment has grown away from the pelvis. Reossification across the diseased joint after displacement osteotomy may occur for three reasons: First, shearing strains are prevented by osteotomy; secondly, ossification is favoured in ischæmic tissue, and ischæmia may be promoted in the femoral head and neck by division of vessels running in the upper end of the femoral shaft; thirdly, as I have attempted to show in a previous paper (*Proc. R. Soc. Med.*, 1946, **39**, 712), the theory of Lavalle and McCrae Aitken may apply and incision of tuberculous bone may of itself be of benefit. I have frequently performed these osteotomies through tuberculous bone or through a tuberculous abscess. So far from harm having been done, considerable improvement has resulted.

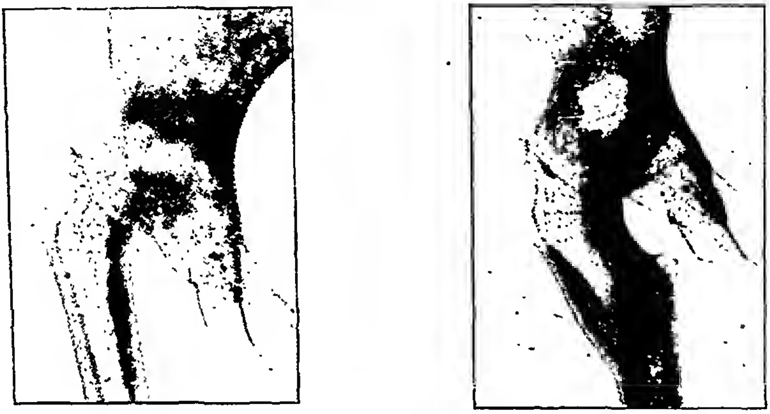

FIG. 1. FIG. 2.

E. H., female. FIG. 1.—Tuberculous hip with unsound ankylosis treated by displacement osteotomy. FIG. 2.—Same hip on late follow-up.

Table I shows the result of displacement osteotomy in 21 patients whose hip disease had become quiescent, but in the majority of whom there had developed some deformity or reactivation of disease. Three of these cases were complicated by the presence of chronic discharging sinuses which had not responded to conservative treatment. There was no delay in bone union following osteotomy, and the hips subsequently became stable with healing of the sinuses.

Children 9, Adults 4	Children 4, Adults 4

In a second series of patients a bone graft was used to augment the displacement osteotomy. An example of this type of osteotomy and graft is shown in figs. 3, 4, 5 (Patient A. H.). I first used the graft as an additional source of osteogenetic tissue, having in mind Lavalle's observation that the results of his operation were better if sliver grafts were inserted into tuberculous bone. The operative method is as follows: An incision is made along the outer and upper aspect of the femoral shaft, and at the tip of the great trochanter it is tailed obliquely backwards in the line of the fibres of the gluteus maximus. In the lower part of the wound the incision is then carried down to the femoral shaft. In the upper part of the wound the gluteal fibres are splinted and retracted. A graft is then cut from the upper end of the femur and great trochanter. The oblique osteotomy is then performed with inward displacement of the upper end of the lower fragment. The osteotome is then passed through that part of the great trochanter which has muscles attached to it so that it and the attached muscles can be lifted up and the upper surface of the femoral neck seen or felt. A gouge is passed along the upper surface of the femoral neck

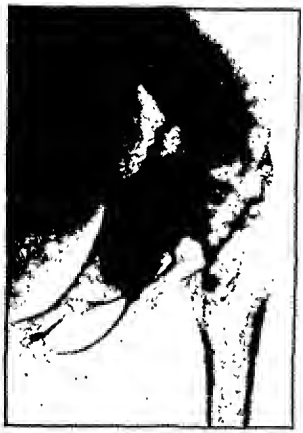

FIG. 3.

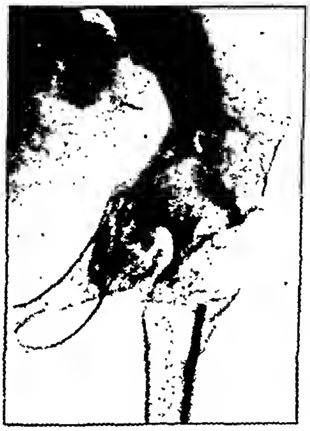

FIG. 4.

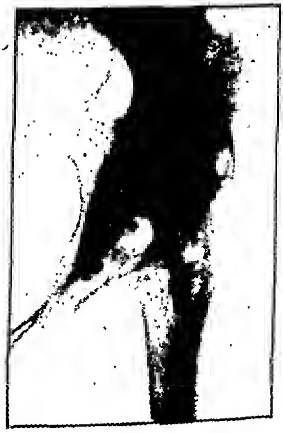

FIG. 5.

A. H., child. FIG. 3.—Pseudarthrosis following tuberculous hip with much destruction of acetabulum.
FIG. 4.—After displacement osteotomy and graft along upper surface of neck. Graft is being absorbed and is difficult to see, but considerable reossification in the destroyed area has occurred.
FIG. 5.—Bony ankylosis and arrested disease less than two years after operation.

into the ilium and a tunnel prepared for the graft. The graft is driven home and the great trochanter replaced over the external end of the graft. Plaster of Paris is applied. No hæmorrhage and very little shock have been encountered in this operation. No plasma infusion or blood transfusion has been necessary following it.

I am grateful to Mr. S. L. Higgs for guidance in developing this operative technique for tuberculous hips. The following table shows the results of this operation, and includes also 4 cases of osteotomy with ischio-femoral graft.

TABLE II.—DISPLACEMENT OSTEOTOMY WITH GRAFT. RESULT OF 12 CASES ONE YEAR OR MORE AFTER OPERATION—TWO PATIENTS STILL WEARING HIP SPLINTS

	Firm ankylosis—stable hip		Unstable hip
	Bone	Fibrous	Fibrous
Osteotomy with graft along upper surface of neck..	5	1	2 (doubtful stability)
Osteotomy with ischio-femoral graft	2	2	0

Finally attention is drawn to the use of osteotomy to promote healing of active tuberculous disease in the hip. Three osteotomies with displacement were performed for patients with active disease, one in an adult, two in children. Osteotomies without displacement were performed for five patients, two of whom were adults and three children. In two of these cases a tuberculous focus in the upper end of the femoral shaft was also curetted. Two of the cases treated by osteotomy and a graft had active disease. In the case of adults these osteotomies were performed rather earlier than in the case of children, but the majority had had a year or more of preliminary conservative treatment. It was possible to discharge the majority of these patients ambulant, about four months after osteotomy; it was necessary to provide them with a well-moulded celluloid hip splint. An example of osteotomy for active disease is seen in the films of D. S. (figs. 6, 7 and 8).

FIG. 7.—Displacement osteotomy after three months' conservative treatment. Acetabular disease beginning to heal. Patient ambulant in celluloid splint.

FIG. 8.—Eighteen months after operation. Disease healed. Hip stable. No splint worn.

Some Points About the Monteggia Fracture

By W. SAYLE CREER, F.R.C.S.

THERE does not appear to be any accepted line of treatment for this awkward fracture, possibly because it is not common enough to provide any one surgeon with a very large series. Only 12 patients out of a total of 20,000 fracture cases seen at my clinics in the past ten years have had a Monteggia fracture.

The chief problem of conservative treatment has been to maintain reduction of the radial head when a good position of the ulna fracture was secured, and vice versa. The management of a number of cases has been simplified by open reduction and internal fixation of the ulna. However, conservative treatment frequently fails to obtain (or to maintain) reduction of the radial head although the ulna is in good position. In such cases late symptoms of pain and difficulty of using the elbow are a constant complaint.

Reconstruction of the orbicular ligament has been urged as a *sine qua non* for this element of the fracture, but any surgeon who has performed it readily appreciates the technical difficulty. Any form of early operation has been condemned because of the dangers of cross-union and of radio-humeral ankylosis. My limited experience is that early operation is not only essential but *per se* carries no such risk.

Of the 12 cases 8 were of the extension type (head of radius forwards), 3 of the flexion type and 1 not stated in the notes. 5 were treated personally and, because of the complaints of those treated conservatively, were submitted to surgery.

In 2 adults internal fixation of the ulna was effected by the passage of a Kirschner wire down the medullary cavity from the tip of the olecranon. The third case was a child and the fracture was in good position and required no internal fixation. On exposing the head of the radius in all 3 cases it was found that the bone had pierced the capsule of the elbow, was tightly gripped by it and was prevented from returning to its normal position by nothing but this structure. In the child although the radial head was displaced forwards the rent was situated posteriorly. No repair of the orbicular ligament was undertaken in any of the cases; but no instability ensued. There was no ankylosis, circum-radial ossification or myositis ossificans.

One case was operated on late—a boy of 5 who was seen six weeks after injury. The fractured ulna had united in good position, but the head of the radius was displaced outwards. There was an associated radial nerve palsy, which recovered with the usual splintage and physiotherapy. Six months after the accident open reduction of the radial head was carried out. Once again the bone was found to have pierced the joint capsule. In this case it might have been wiser to explore and attempt to repair or replace the orbicular ligament for, although the radial head appeared to be stable after suture of the muscles, it is now, four years later, unstable and displaced anteriorly. Elbow movements are only 70 degrees to 140 degrees, with pronation 30 degrees and supination 60 degrees. The boy and his parents think the result is good.

Another method of treating it would have been to excise the radial head. This was done four months after injury in a case treated conservatively elsewhere. The result has been extremely satisfactory for his only disability is the loss of 5 degrees of extension.

Early operation was followed by cross-union in one case. This was a man of 47 who was kicked by a horse and suffered a fracture of the extension type. Eight days later the ulna was reduced and fixed by a plate through one incision, and the head of the radius reduced through a separate one. As in the other cases the head of the radius had passed through a rent in the capsule and, when brought back into the joint, was stable. This man developed cross-union of radius and ulna. It is difficult to decide whether the cross-union should be ascribed to the operation or to the trauma. A kick from a horse on the forearm is probably as severe in its effects on the soft tissues as when a motor cycle rider suffers a compound fracture of the tibia due to direct violence. The cross-union may have resulted from a widespread hæmatoma due to the primary injury.

The "boutonnière" dislocation, especially of the thumb and at the shoulder, is well known to orthopædic surgeons as an indication for open reduction, but appears to have been overlooked in the management of the Monteggia fracture. Difficulty of reduction of any joint dislocation should always suggest this type of capsular tear and is a strong indication for early recourse to surgery. The alleged dangers of permanent stiffness consequent on early open reduction have probably been exaggerated. The following case of a postero-lateral dislocation of the elbow without fracture in a man of 45 is an example of a good result following early surgery. Three attempts at reduction by my registrar failed. Sixteen days after injury open reduction revealed that the whole of the lower end of the humerus had passed through a rent in the front of the joint capsule. The opening was enlarged and reduction revealed that the whole of the lower end of the humerus had passed 30 degrees of movement from the fully straight position was possible afterwards although he was still anæsthetized; but twelve months later he has elbow movement from 70 degrees to 180 degrees, 40 degrees of pronation and full supination, and X-rays show ligamentous ossification no more extensive than seen after every case of dislocated elbow.

Conclusions from these twelve cases of Monteggia fracture: (1) Open reduction of the radial head is frequently necessary—the "boutonnière" rent bars reduction. Repair of the orbicular ligament in the early cases does not seem essential. (2) Internal fixation of the ulna may be needed. (3) For the late case excision of the unreduced radial head gives a good result. (4) The danger of radio-humeral ankylosis or myositis ossificans consequent on early operation has been given undue prominence.

President: SYDNEY THOMSON, M.D.

[*November* 21, 1946]

Ulcer of Vulva in Young Girl.—M. MOORE WHITE, M.D. (*By kind permission and in conjunction with* R. T. BRAIN, F.R.C.P.).

M. R., aged 17, was first seen on August 2, 1945, with an ulcer involving the right labium major and minor. She gave a history of ulcers in the mouth since the age of 3 and small ulcers on the vulva during the previous year which had healed without treatment. The amount of œdema present had varied as also the appearance of tender nodular areas adjoining the ulcer and posteriorly on the opposite labia. There was no history of vaginal discharge. Menstruation was regular except for a short time after admission. Katamenia at 14. Nothing relevant in past history. Strong family history of rheumatism. The girl was well-built and of healthy appearance. There were several red ulcers on the inner side of the cheek and lower lip. The fauces were not injected. An ulcerated area 2 in. × 1 in. involved the right labium minor and major posteriorly. It possessed a central slough and a hyperæmic edge, with some surrounding œdema. The ulcer was tender to touch. She was virgo intacta. There was no vaginal discharge. She had mild pyrexia for five days and for a short similar period later.

Wassermann, Kahn and gonococcal complement-fixation tests were negative. Subsequently the parents and a brother underwent the routine tests for venereal infection, which were all negative. The blood-count was normal. The E.S.R. was raised and has varied between 39 and 42 mm. fall in one hour (Wintrobe method).

A direct film from the ulcers in the mouth showed mixed organisms, fusiform bacilli and a few spirochætes. Culture: *Staphylococcus aureus, Streptococcus viridans* and *N. catarrhalis.* A direct film from the vulval ulcer showed Gram-positive and negative rods, and Gram-positive cocci and diplococci. Culture: *Staphylococcus aureus* (coagulase-positive and moderately penicillin-sensitive) and *Staphylococcus albus.* Frei-Hoffmann test was negative. No Donovan bodies were found. Tuberculosis, diphtheria and anaerobic infection were excluded. A biopsy was taken in September 1945. The report stated that the section showed delicate fibrous tissue thickly infiltrated with lymphocytes, plasma cells, macrophages and a few polymorphonuclear cells.

Dr. M. Löwenberg reported on a section taken in November 1945 that "diplococci, isolated and in groups and placed both extra- and intra-cellularly were present, which were not unlike gonococci in situation and in staining properties.... They resembled the gonococci found in prostatic and cervical lesions of long-standing, rather than the organisms found in recent mucosal lesions, since they were somewhat decreased in size and the Gram stain gave unreliable results, in that in the same section some diplococci were stained and others discoloured. They were best shown with Unna's polychrome methylene-blue; with this stain they showed the characteristic dark blue colour". He considered characteristic of a gonococcal lesion the presence of vesicles in the section, absence of elastic tissue and intracellular œdema.

A more recent biopsy, October 1946, reported chronic ulceration with no characteristic appearance of a gonococcal infection and no organisms present.

All tests for venereal disease were negative. Tests were later repeated and found negative by Dr. M. Shaw at the Royal Free Hospital who commented that the ulcer did not conform to those typical of venereal disease. She had seen one of a similar nature due to *B. crassus*, Döderlein's bacillus.

Local treatments include triple dye, various sulphonamide preparations, penicillin, propamidine, zinc peroxide, X-rays (one application only, 100 *r*).

The general treatments include administration of vitamins A, B, C and D in large doses. Course of N.A.B. 4·5 grammes. Sulphonamides, systemic penicillin 1,700,000 units. T.A.B. and gonococcal vaccines. Stilbœstrol.

My thanks are due to Dr. R. T. Brain, Dr. Mary Michael Shaw and Dr. Elizabeth Hunt for their help and advice with regard to this case and to Professor Webb for the numerous investigations and reports undertaken by his Pathology Department at the Three Counties Emergency Hospital and at the Royal Free Hospital.

Comment.—The girl was 15½ when admitted. She was not interested in the opposite sex, so that if the lesion were gonococcal it must have been innocently contracted. Gram-positive and Gram-negative diplococci have been isolated from the vulval smear on several occasions but have never been found intracellularly. Dr. Löwenberg, however, was able to isolate an intracellular diplococcus from a biopsy section which he demonstrated to Dr. Brain and myself. The organism stained deeply with Unna's polychrome methylene-blue, with Gram stain some took the stain, some appeared discoloured only. According to Dr. Löwenberg the section showed other morphological features characteristic of a gonococcal infection—notably vesicle formation in the epidermis, absence of elastic tissue and cellular infiltration more marked in the deeper layers.

Had the lesion been gonococcal one would have expected some response to penicillin, sulphonamides, T.A.B. and gonococcal vaccine.

It has been suggested by Dr. Hunt that the lesion resembles those observed in cases of erythema multiforme. The association with ulcers of the mouth, the history of recurrence, the presence of painful nodular areas adjoining the ulcer on the vulva from time to time, and the rheumatic family history support this diagnosis.

The possibility of dermatitis artefacta has been excluded.

Dr. R. T. Brain: I have observed this patient since 1945; her lesions are similar to those observed in other cases I have had in which bacteriological studies have failed to establish the ætiology of the condition and treatment has been of no avail. Since the patient started with small recurrent ulcers in the mouth and on the vulva one has to consider first of all the different varieties of recurrent ulcers. These can be classified as follows: (1) Aphthous ulcers which may be due to herpes simplex, monilia infections, or a group of obscure ætiology. These ulcers are usually small and recurrent, and healing is not usually delayed. (2) A rare condition called "*peri-adenitis mucosa necrotica recurrens*", as described by Sutton and others, usually beginning with firm subcutaneous nodules affecting the buccal or vulval mucosa. As a rule these ulcers are said to heal in a week or two, although sometimes they may persist for a year or longer. (3) Ulcus vulvæ acutum of Lipschutz is usually associated with infection with *B. crassus*, which, however, may not be of pathological significance, and in this case was not found. (4) Erythema multiforme bullosa may be followed by superficial ulceration, but the early eruptions do not present any difficulty and the subsequent ulceration is not commonly persistent.

The present case may now be regarded as presenting a chronic ulcer of the vulva and other conditions must be considered. (1) Tuberculosis usually produces a more deeply-coloured ulcer with undermined edges. The histology is fairly characteristic and tubercle bacilli may be found. In this case these findings were negative. (2) Actinomycosis would present a different clinical picture, and the organism was not found. (3) Tertiary syphilis has been excluded by blood tests and arsenotherapy. (4) Diphtheritic ulcers, the organism is usually found without difficulty. (5) Diphtheroid ulceration, in which the organisms are abundant although the pathogenicity of the diphtheroid bacillus is not generally accepted. (6) Ulcus molle, which was excluded because Ducrey's bacillus was not discovered, and, as in the next condition also, glandular involvement is a prominent feature. (7) Lymphogranuloma inguinale was excluded by tests with Frei's antigen as well as by the clinical picture. Finally, there are two conditions of chronic non-specific ulceration; namely, chronic simple ulcer of the vulva usually occurring with venereal infection in prostitutes, and phagedenic ulceration in which extending necrosis is more severe and progressive than in the present condition.

Dr. J. T. Ingram: Since Gram-negative organisms may be a cause of this condition I would suggest trying the effect of ½% parachlorophenol either alone or in penicillin cream.

Dr. J. E. M. Wigley; I favour the diagnosis of peri-adenitis mucosa necrotica. I have seen one or two cases affecting both the mouth and the vulva which have persisted for a number of years. One of them, I remember, was seen at intervals for six or seven years. The patient was always quite satisfied that the lesions of the mouth were healed by a very small dose of X-rays.

Dr. H. W. Barber: I was unable to examine this case properly, but I gather there has been recurrent ulceration of the mouth as well as of the vulva. The more likely diagnosis, I think, is that suggested by Dr. Wigley, which is the same condition as that described by Lipschutz.

When fully developed and unaltered by secondary infection, the ulcers, whether in the mouth or on the vulva, are distinctive, the circular raised and indurated border and the central plug resulting from necrosis being characteristic. I have never accepted Lipschutz' view that infection with *B. crassus* is responsible, and agree with Whitwell, G. P. B. (1934, *Brit. J. Derm.*, *46*, 414) that it is probably a virus disease.

As with herpes simplex, in females there seems sometimes to be a relationship with ovarian function, and the disease may begin for the first time at or after the menopause. In two such cases the ulcers ceased to appear after œstrogenic therapy was given over a period of some months. In younger women, as with herpes, the ulcers may occur chiefly just before the periods. In one case œstrogens given during the period and the first half of the intermenstrual period appeared to prevent involvement of the vulva, but the buccal ulcers continued, and they did not cease to form during pregnancy. In another case, however, complete remission followed such treatment.

I have recently seen my first case of the disease in which there were ocular symptoms—Behcet's syndrome. The patient is the wife of a medical man, and the eye condition was fully described to me by Mr. Savin. She is at present being treated with vaccinia virus.

Multiple Tuberculides, including the Scleroderma-like Form of Erythema Induratum.—H. W. Barber, M.B.

Mrs. F. B., aged 58.

Operations for tuberculous cervical adenitis at 9 and 12 years of age. In 1926 operations by Sir Harold Fairbank for tuberculous arthritis of the left shoulder-joint and tuberculosis of a metacarpal bone of the left hand. Four years ago operation for tuberculous ribs.

For twenty years she has been subject to recurrent attacks of erythema nodosum.

For about three years she has had recurrent nodules of erythema induratum, pigmented remains of which may be seen on the thighs and legs, and at her first visit to me (October 9, 1946) two of these nodules in the subsiding stage were present on the outer side of the right thigh.

The scleroderma-like areas on the right sole, inner side of the foot, and ankle, and on the inner side of the lower part of the left leg have been present for about two years.

In the past year, multiple patches of lichen scrofulosorum have appeared from time to time.

rather than the organisms found in recent mucosal lesions, since they were somewhat decreased in size and the Gram stain gave unreliable results, in that in the same section some diplococci were stained and others discoloured. They were best shown with Unna's polychrome methylene-blue; with this stain they showed the characteristic dark blue colour". He considered characteristic of a gonococcal lesion the presence of vesicles in the section, absence of elastic tissue and intracellular œdema.

A more recent biopsy, October 1946, reported chronic ulceration with no characteristic appearance of a gonococcal infection and no organisms present.

All tests for venereal disease were negative. Tests were later repeated and found negative by Dr. M. Shaw at the Royal Free Hospital who commented that the ulcer did not conform to those typical of venereal disease. She had seen one of a similar nature due to *B. crassus,* Döderlein's bacillus.

Local treatments include triple dye, various sulphonamide preparations, penicillin, propamidine, zinc peroxide, X-rays (one application only, 100 r).

The general treatments include administration of vitamins A, B, C and D in large doses. Course of N.A.B. 4·5 grammes. Sulphonamides, systemic penicillin 1,700,000 units. T.A.B. and gonococcal vaccines. Stilbœstrol.

My thanks are due to Dr. R. T. Brain, Dr. Mary Michael Shaw and Dr. Elizabeth Hunt for their help and advice with regard to this case and to Professor Webb for the numerous investigations and reports undertaken by his Pathology Department at the Three Counties Emergency Hospital and at the Royal Free Hospital.

Comment.—The girl was 15½ when admitted. She was not interested in the opposite sex, so that if the lesion were gonococcal it must have been innocently contracted. Gram-positive and Gram-negative diplococci have been isolated from the vulval smear on several occasions but have never been found intracellularly. Dr. Löwenberg, however, was able to isolate an intracellular diplococcus from a biopsy section which he demonstrated to Dr. Brain and myself. The organism stained deeply with Unna's polychrome methylene-blue, with Gram stain some took the stain, some appeared discoloured only. According to Dr. Löwenberg the section showed other morphological features characteristic of a gonococcal infection—notably vesicle formation in the epidermis, absence of elastic tissue and cellular infiltration more marked in the deeper layers.

Had the lesion been gonococcal one would have expected some response to penicillin, sulphonamides, T.A.B. and gonococcal vaccine.

It has been suggested by Dr. Hunt that the lesion resembles those observed in cases of erythema multiforme. The association with ulcers of the mouth, the history of recurrence, the presence of painful nodular areas adjoining the ulcer on the vulva from time to time, and the rheumatic family history support this diagnosis.

The possibility of dermatitis artefacta has been excluded.

Dr. R. T. Brain: I have observed this patient since 1945; her lesions are similar to those observed in other cases I have had in which bacteriological studies have failed to establish the ætiology of the condition and treatment has been of no avail. Since the patient started with small recurrent ulcers in the mouth and on the vulva one has to consider first of all the different varieties of recurrent ulcers. These can be classified as follows: (1) Aphthous ulcers which may be due to herpes simplex, monilia infections, or a group of obscure ætiology. These ulcers are usually small and recurrent, and healing is not usually delayed. (2) A rare condition called "peri-adenitis mucosa necrotica recurrens", as described by Sutton and others, usually beginning with firm subcutaneous nodules affecting the buccal or vulval mucosa. As a rule these ulcers are said to heal in a week or two, although sometimes they may persist for a year or longer. (3) Ulcus vulvæ acutum of Lipschutz is usually associated with infection with *B. crassus,* which, however, may not be of pathological significance, and in this case was not found. (4) Erythema multiforme bullosa may be followed by superficial ulceration, but the early eruptions do not present any difficulty and the subsequent ulceration is not commonly persistent.

The present case may now be regarded as presenting a chronic ulcer of the vulva and other conditions must be considered. (1) Tuberculosis usually produces a more deeply-coloured ulcer with undermined edges. The histology is fairly characteristic and tubercle bacilli may be found. In this case these findings were negative. (2) Actinomycosis would present a different clinical picture, and the organism was not found. (3) Tertiary syphilis has been excluded by blood tests and arsenotherapy. (4) Diphtheritic ulcers, the organism is usually found without difficulty. (5) Diphtheroid ulceration, in which the organisms are abundant although the pathogenicity of the diphtheroid bacillus is not generally accepted. (6) Ulcus molle, which was excluded because Ducrey's bacillus was not discovered, and, as in the next condition also, glandular involvement is a prominent feature. (7) Lymphogranuloma inguinale was excluded by tests with Frei's antigen as well as by the clinical picture. Finally, there are two conditions of chronic non-specific ulceration; namely, chronic simple ulcer of the vulva usually occurring with venereal infection in prostitutes, and phagedenic ulceration in which extending necrosis is more severe and progressive than in the present condition.

Dr. J. T. Ingram: Since Gram-negative organisms may be a cause of this condition I would suggest trying the effect of ½% parachlorophenol either alone or in penicillin cream.

Dr. J. E. M. Wigley; I favour the diagnosis of peri-adenitis mucosa necrotica. I have seen one or two cases affecting both the mouth and the vulva which have persisted for a number of years. One of them, I remember, was seen at intervals for six or seven years. The patient was always quite satisfied that the lesions of the mouth were healed by a very small dose of X-rays.

Dr. H. W. Barber: I was unable to examine this case properly, but I gather there has been recurrent ulceration of the mouth as well as of the vulva. The more likely diagnosis, I think, is that suggested by Dr. Wigley, which is the same condition as that described by Lipschutz.

When fully developed and unaltered by secondary infection, the ulcers, whether in the mouth or on the vulva, are distinctive, the circular raised and indurated border and the central plug resulting from necrosis being characteristic. I have never accepted Lipschutz' view that infection with *B. crassus* is responsible, and agree with Whitwell, G. P. B. (1934, *Brit. J. Derm.*, 46, 414) that it is probably a virus disease.

As with herpes simplex, in females there seems sometimes to be a relationship with ovarian function, and the disease may begin for the first time at or after the menopause. In two such cases the ulcers ceased to appear after œstrogenic therapy was given over a period of some months. In younger women, as with herpes, the ulcers may occur chiefly just before the periods. In one case œstrogens given during the period and the first half of the intermenstrual period appeared to prevent involvement of the vulva, but the buccal ulcers continued, and they did not cease to form during pregnancy. In another case, however, complete remission followed such treatment.

I have recently seen my first case of the disease in which there were ocular symptoms—Behcet's syndrome. The patient is the wife of a medical man, and the eye condition was fully described to me by Mr. Savin. She is at present being treated with vaccinia virus.

Multiple Tuberculides, including the Scleroderma-like Form of Erythema Induratum.—H. W. Barber, M.B.

Mrs. F. B., aged 58.

Operations for tuberculous cervical adenitis at 9 and 12 years of age. In 1926 operations by Sir Harold Fairbank for tuberculous arthritis of the left shoulder-joint and tuberculosis of a metacarpal bone of the left hand. Four years ago operation for tuberculous ribs.

For twenty years she has been subject to recurrent attacks of erythema nodosum.

For about three years she has had recurrent nodules of erythema induratum, pigmented remains of which may be seen on the thighs and legs, and at her first visit to me (October 9, 1946) two of these nodules in the subsiding stage were present on the outer side of the right thigh.

The scleroderma-like areas on the right sole, inner side of the foot, and ankle, and on the inner side of the lower part of the left leg have been present for about two years.

In the past year, multiple patches of lichen scrofulosorum have appeared from time to time.

The climacteric occurred at the age of 50 and she still has hot flushes. On the face and upper part of the neck are seen the pigmentation and telangiectasia described by Civatte, and usually known as "pigmented and reticular poikilodermia of the face and neck".

The patient is now in Nuffield House for investigation.

Blood-count.—Hypochromic anæmia (Hb 65%) with moderate anisocytosis and anisochromia. Polynucleosis without left shift.

B.S.R.—One-hour reading 56 mm.; two-hour reading 91 mm.

Films very streaky, indicating that B.S.R., after correction for anæmia, is markedly raised.

Urine: No abnormality except excess of indican.

Radiogram of chest: No evidence of disease of the lungs. Heart and mediastinal shadows are normal.

A Mantoux tuberculin test was made on November 16, 1946. There was no local reaction on November 18, but a typical eruption of erythema nodosum had occurred around the left knee, and was recognized by the patient as similar to those she had had periodically for twenty years.

A cutaneous test with tuberculin jelly was made on the right side of the back, and a control test on the left side (November 16, 1946). When examined on November 18, a typical outbreak of papules of lichen scrofulosorum had appeared on the site to which the tuberculin jelly was applied. Moreover a new patch of this eruption had occurred on the right thigh.

The most interesting lesions are the indurated plaques situated on the right sole, inner side of the right foot and ankle, and on the inner side of the left leg above the ankle. At the margins of the plaque on the right foot are raised, reddened nodules, extremely tender on pressure. The central part is white and hard, simulating morphœa. At points areas of necrosis have occurred with serous discharge.

The indurated plaque on the left leg is in part reddened on the surface, but palpation above it reveals extension of the induration, covered by normally coloured skin.

Exfoliative Erythrodermia with Marked Pigmentation.—J. E. M. WIGLEY, M.B.

E. R., male, aged 55.

History.—Dates from 1940 with the eruption apparently beginning on the right hand. In 1941-46 he attended St. Mary's Hospital as an out-patient from whence he was admitted to Paddington Hospital in May 1946 with a diagnosis of exfoliative dermatitis.

On examination.—At that time he had an almost universally red, slightly œdematous, scaling and much excoriated skin. There were a few weeping and bleeding areas, principally resulting from scratching. Irritation was very severe and difficult to control. The lymphatic glands in his neck, axillæ and groins were easily palpable. His liver and spleen were not palpable and general physical examination revealed no other abnormality. A blood-count at that time showed: R.B.C. 4,700,000; Hb 87%; C.I. 0·92; W.B.C. 32,000. Differential count: Polys. 61%, eosinos. 22%, lymphos. 10%, monos. 7%.

Since admission his progress has been variable. In June he had an attack of lobar pneumonia which responded to the usual treatment, and in October an attack of herpes zoster affecting the tenth dorsal segment on the right side. His skin has slowly lost its redness and become smooth, almost leathery, and appears stretched over his thorax. He has developed a remarkable brownish pigmentation which is almost universal, though it is noticeable that the area which was affected by the zoster is quite white. The irritation has almost ceased.

Numerous blood-counts have shown some variations from the normal. A moderate degree of lymphocytosis has been somewhat marked lately whilst there has been a fairly persistent eosinophilia. The following are examples:

	July 1	Aug. 12	Oct. 8	Nov. 15
W.B.C.	... 11,500	17,000	7,400	10,000
Polys.	... 52%	56%	58%	75%
Eosinos.	... 29%	25%	16%	3%
Lymphos.	... 16%	15%	22%	20%
Monos.	... 3%	4%	4%	2%

The Wassermann and Kahn tests are negative.

July 17: *Sternal puncture.*	N.	E.	B.
Polys.	43·5	5·5	—
Metamyelos.	4·5	1	—
Myelos.	12	10	0·5

Premyelocytes 2, myeloblasts 0, lymphocytes 2, monocytes 0, normoblasts 16·5, erythroblasts 2, megaloblasts 0·5.

Total nucleated cells—125,000 per c.mm. (normal 25,000—100,000).

Myeloid erythroblast ratio = 4·2 : 1 (normal) 8 : 1 to 2 : 1). B.P. 110/70.

Radiographic examination of his gastro-intestinal tract, made on account of his marked loss of weight, showed no evidence of neoplasm.

Urethane in 1 gramme doses t.d.s. seems to give a little relief and improvement.

Biopsy.—Skin: The epidermis is thickened and the superficial parts of the corium contain a marked increase of lymphoid cells, few reticulum cells and many eosinophils, situated chiefly around the blood-vessels, suggestive of a chronic lichenified dermatitis. There is really no evidence in the section alone to suggest a blood disorder.

Gland: The main feature of this lymphatic gland is severe active chronic inflammation. There are some granulomatous-looking areas which I cannot assign to any specific condition. They are rather better defined than one would expect in Hodgkin and more spindle-celled and less infiltrated than the examples we have of mycosis fungoides; this latter cannot be excluded, especially in view of the erythrodermia.

Comment.—The case is difficult to classify. It may yet develop into a leukæmia, and belong to the group of the reticulo-endothelioses. Addison's disease appears to be ruled out and no evidence of malignant disease was discovered. The patient looks ill though he persists in saying he feels better than he did on admission.

POSTSCRIPT.—Since the meeting his general condition has improved very much. His skin is still deeply pigmented.

Dr. A. C. Roxburgh: Is the pigment melanin?

Dr. Wigley: It was not remarked on in the section, but it is most likely melanin.

Dr. Brian Russell: In glandular biopsies on males, of between 60 and 70, with exfoliative erythroderma, Dr. Robb-Smith reports that he finds characteristic reactive changes of marked proliferation of histiocytes in the sinuses and also in the perisinusoidal tissue with many eosinophils and much melanin, a condition described by French as lipo-melanic reticulosis.

Dr. F. Parkes Weber: This slaty pigmentation makes me think of the possibility of argyria. An attempt at spectrographic diagnosis might be worth while.

Dr. Wigley: I thank Dr. Parkes Weber for his suggestion. The question of the pigmentation being the result of the ingestion or use of silver was thought of but the evidence did not support this at all.

The climacteric occurred at the age of 50 and she still has hot flushes. On the face and upper part of the neck are seen the pigmentation and telangiectasia described by Civatte, and usually known as "pigmented and reticular poikilodermia of the face and neck".

The patient is now in Nuffield House for investigation.

Blood-count.—Hypochromic anæmia (Hb 65%) with moderate anisocytosis and anisochromia. Polynucleosis without left shift.

B.S.R.—One-hour reading 56 mm.; two-hour reading 91 mm.

Films very streaky, indicating that B.S.R., after correction for anæmia, is markedly raised.

Urine: No abnormality except excess of indican.

Radiogram of chest: No evidence of disease of the lungs. Heart and mediastinal shadows are normal.

A Mantoux tuberculin test was made on November 16, 1946. There was no local reaction on November 18, but a typical eruption of erythema nodosum had occurred around the left knee, and was recognized by the patient as similar to those she had had periodically for twenty years.

A cutaneous test with tuberculin jelly was made on the right side of the back, and a control test on the left side (November 16, 1946). Since admission his progress has been variable. In June he had an attack of lobar pneumonia which responded to the usual treatment, and in October an attack of herpes zoster affecting the tenth dorsal segment on the right side. His skin has slowly lost its redness and become smooth, almost leathery, and appears stretched

Leiomyoma Cutis.—G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P., and M. H. SMALL, M.R.C.S., L.R.C.P.

Miss D. C., aged 43.

Nodules first appeared on the right forearm in 1928, and have gradually become more numerous, although the original ones have not increased in size to any marked degree. When the skin is warm the nodules take on a red appearance, and are white when the skin is cool.

Present appearance.—The eruption is distributed over the forearms, face and neck, and there are a few nodules on the chest, abdomen and thighs. There are pink raised lesions; some papular, others nodular; some being elongated. The nodules are about the size of a half pea. The surface is smooth and glistening. There are no scales. On palpation they are of a firm consistence, almost rubbery. There is no tenderness. At first sight, the condition was thought to be sarcoidosis. The small nævoid nodules on the face first made their appearance about a year ago.

Past history.—1927: Bronchopneumonia. 1928: Burns of chest, with much scarring but no keloid formation. 1933: Erysipelas of face. 1939: Panhysterectomy and appendicectomy.

Family history.—Mother alive and well. Father died of pneumonia, 1906. Three sisters alive and well.

Investigations.—W.R. negative. Biopsy and section: Typical leiomyoma cutis. X-ray report: No abnormality detected in chest, hands or feet.

Erythrodermia in Lymphatic Leukæmia. (Malignant Erythrodermia).—G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P., H. CORSI, F.R.C.S., and K. D. CROW, M.R.C.P.

F. W., 79 years, very deaf man.

The condition started with generalized pruritus seventeen months ago. One year ago generalized erythrodermia with fine, branny scaling and intense burning, which lasted for three months. Remission, with subsiding scaling and erythrodermia, but continued pruritus, lasted for nine months. Enlarged, painless glands appeared in the neck, axillæ and groins. Three months ago erythrodermia recurred, rather worse, with larger and more extensive scaling, and considerable enlargement of cervical and inguinal glands, as well as in the axillæ. Two months ago ectropion with epiphora developed and the patient complained of his "skin being too tight". Neuralgic pains in the right side of the head were only relieved by morphia.

Blood-count.—W.B.C. 26,400: polys. 8,448, lymphos. 16,368, monos. 1,320, eosinos. 264 per c.mm.

The skin is now universally red, especially over the head, neck and trunk, is covered with fine scales, and is diffusely thickened. All lymph glands are enlarged, most conspicuously the inguinal ones. The mouth and the nails are normal, spleen not enlarged, but liver is easily palpable. X-ray of the chest showed left ventricular hypertrophy, and generalized bronchitis, but no hilar node enlargement. Barium meal, on account of abdominal pain and constipation, showed nothing abnormal.

Treatment.—Radiotherapy, and arsenic by mouth, have caused the glands to diminish in size, and relieved the pain and pruritus considerably.

Hæmatology and Pathology.—(Dr. E. NEUMARK.)

Hæmatologically and histopathologically this case is one of lymphatic leukæmia.

Impetigo Herpetiformis. ? Pemphigus Vegetans.—J. E. M. Wigley, M.B.

P. B., male, aged 56.

History.—The eruption first appeared in May 1946 on the left calf as a white bleb surrounded by smaller spots. Fresh areas appeared over the leg, extending to the other leg, to the trunk, shoulder region, and the face. There has been some irritation, not at any time severe, and his general health has remained good. There is no history of asthma, hay-fever, or skin disease in his family. His work does not entail any special industrial risks.

On admission to hospital in August he presented a remarkable picture. The lesions were roughly of two types: the more numerous ones consisted of a round, roughened, and crusted area varying in size from ¾ to 1½ inches with concentric, incomplete rings of pustules and minor blisters containing purulent fluid surrounding it. On each shoulder, spreading to the sides of the neck, were considerable areas of reddened skin surrounded by an irregular margin of similar pustules and small blisters. Over the whole of these surfaces were irregular lines of purulent blisters giving an almost lattice-work appearance. The background of both types of lesion showed varying degrees of pigmentation which appeared to darken in colour as the blisters faded away. To-day the areas on the shoulders are represented by pigmentation only. It is noticeable that the anogenital region and the mouth are not affected.

Cultures from the blisters revealed *B. coli* on one occasion and a mixture of *Staphylococcus aureus* and hæmolytic streptococci on more than one occasion.

Treatment.—External application of penicillin cream produced no change and a course of 125,000 units of systemic penicillin was ineffective. Since September he has been taking sulphadiazine, 1 gramme per day, and there appears to be slow but definite improvement in his condition.

I have not seen a clinical picture quite like this before but the lesions reminded me strongly of some coloured illustrations in one of the older dermatological atlases in which the name of the condition was given as impetigo herpetiformis. It also seems to fit in with the description of that condition given in Ormsby and Montgomery's "Diseases of the skin," 1943. The condition was originally described by Hebra in 1872 and subsequently by various other authors. Although more frequently seen during pregnancy it has also been reported in non-pregnant males, as in this case.

I shall be interested to see if this case will develop into a true pemphigus vegetans.

Dr. L. Forman: I have seen two similar cases, commencing with vegetative lesions on the scalp and both regarded as pemphigus vegetans. In each case superficial ulceration developed in the mouth mimicking secondary specific mucous patches. Large vegetating plaques developed in the flexures of the armpits and groins, and over the trunk. One case has cleared completely after eighteen months in hospital and has remained well for five months. The other patient made considerable improvement in about the same time.

Papulo-Necrotic Tuberculides.—Louis Forman, M.D.

R. G., male, aged 13 years.

1943, tuberculous glands removed. Operation followed by pericardial effusion. Rash appeared May 1946, cleared, but relapsed October 1946.

X-ray chest negative.

The boy shows Fröhlich's adiposity; right testicle not palpable. There is a very profuse eruption over arms, buttocks and thighs, of small red papules, vesicular, pustular and necrotic. Over the back there are grouped, skin-coloured papules of lichen scrofulosorum. Small pitted scars are seen over limbs and face. Tuberculin jelly patch test strongly positive, the reaction being a grouped papular one, mimicking the lichen scrofulosorum already present.

I have one case of leukæmia alive and well after six years, so that long remissions at least are not unknown.

Dr. Mitchell-Heggs: This man complained of very severe neuralgia of uncertain origin. It resisted all ordinary treatment, but as soon as the X-ray treatment of the glands made itself felt and the glands began to get smaller, the pain disappeared.

? Epidermodysplasia of Lewandowski and Lutz. ? Abortive Form of Blastomycosis or Chromoblastomycosis.— H. W. Allen, D.M.

G. M., butcher and farmer, aged 59 years, came to see me first in July for a warty condition of his hands. The condition is not hereditary. There is no consanguinity of parents. His previous history included slight rheumatism of the upper limbs and slight patches of pityriasic dermatitis of scalp. The present trouble started as warts, which never caused irritation.

On examination.—The clinical picture was not that of a verrucose blastomycosis or chromomycosis, and certainly not that of verrucæ vulgares. The distinguishing characteristics were those of epidermodysplasia verruciformis, i.e. very small warty lesions, often flat-topped, occasionally grouped, chiefly affecting the hands symmetrically, but differed in that the dorsum of the hand was not affected as is usual, and by the characteristic minute brown ring which could be shown on diascopy to outline a lesion sharply.

Scraping of the lower layers followed by teasing out in saline enabled me to demonstrate the mycelium and double-contoured occasionally brownish cells of a blastomyces or zymonema.

Culture gave a perfect white fluffy growth, which from previous experience, and by reference to illustrations in Sutton's textbook, I should classify as a blastomyces.

The culture has disappeared, and, as anticipated, X-ray treatment has made it impossible to repeat it.

Treatment.—I asked Dr. Charles Wroth of Exeter kindly to give ¾ B (i.e. ¾ pastille dose) at the earliest possible moment. As a result there was improvement; he gave prolonged treatment, and wrote on October 25 that "the skin condition of the hands and wrists has cleared up satisfactorily, but the numerous minute nodules of hard skin (? warts) although smaller, have not completely disappeared". Prolonged X-ray treatment has failed to clear up the condition.

It is regrettable that no biopsy was obtained at the first visit, particularly as it is possible that X-ray therapy has permanently affected the characteristic microscopic structure.

Dr. J. E. M. Wigley: I should have thought lichen planus was the most likely diagnosis here.

Dr. F. Parkes Weber: I must say that I have not seen the original account by Lewandowski and Lutz, but, judging by the name, "epidermodysplasia verruciformis", this case must be vastly different from what they described under that heading. The patient is 59 years old, and if he has only just begun to have the disease—for the last half-year, I think he told me—it would be rather late in life to develop a dysplasia. I think that Dr. Wigley's diagnosis holds the field.

Dr. A. C. Roxburgh: I support the diagnosis of lichen planus.

A Hereditary Ectodermal Dysplasia, Hitherto Not Described, Including Grouped Comedones.—C. H. Whittle, M.D.

D. B., a married woman, aged 40.

The patient has had this thick rather dry skin and grouped comedones since puberty. They are most noticeable at the root of the nose, in the naso-labial folds, on the chin, on the shoulders, in the axillæ, on the breasts, in the groins, in the bends of the elbows, on the fronts of the knees. There is one cutaneous horn on the left cheek.

In all essentials it resembles the cases of Panton and Sequeira (*Quart. J. Med.* (1925), **18,** 250), MacCormac and Whitby (*Proc. R. Soc. Med.* (1936), **30,** 192), MacCormac (*Proc. R. Soc. Med.* (1928), **21,** 1171) and other authors.

Blood-count (7.11.46).—R.B.C. 4,100,000 per c.mm.; Hb 80% (12 grammes); C.I. 1; mean cell diameter (halometer) 7·1 μ; W.B.C. 28,000 per c.mm. Polys. 31% (8,100 per c.mm.), lymphoid cells 67% (18,700 per c.mm.), mononuclears 2% (560 per c.mm.). The predominating cell was the mature-looking, small lymphocyte. Some cells were very large and primitive-looking, and contained a number of nucleoli, their cytoplasm being mainly basophilic, sometimes vacuolated and with pseudopodic processes. Numerous mitotic figures were seen which were mainly atypical in shape, a most unusual phenomenon in lymphoid cells. Supravital preparations with neutral red and Janus green showed most cells to be non-motile and non-granular, confirming their lymphoid character.

Sternal marrow examinations showed 75% of the cells to be lymphoid, the normal being 5% to 20%, but basket cells were not prominent in either blood or marrow films.

Pieces of skin examined histologically showed some parakeratosis, little hyperkeratosis, and some spongiosis. The lymphatic infiltration extends into the superficial layer of the epithelium. There are many melanophores and many giant cells, which appear to destroy the elastic. The elastic fibres in the intermediate zone stain badly and are coarsened throughout, resembling those seen in pseudoxanthoma elasticum.

A gland excised from the right groin did not present the usual follicular pattern, but consisted of sheets of cells, staining darkly, with round nuclei. The glandular capsule is infiltrated and, in places also, the sinuses. There are many large reticulum cells. The appearances are those of lymphatic leukæmia.

Diagnosis in this case is based on clinical grounds ("homme rouge"), glandular enlargement, &c., and on the blood findings confirmed by sternal marrow biopsy, and on the histology of the skin and of a lymph gland.

Dr. J. E. M. Wigley: I think there is a relatively small group of cases which can be recognized clinically and which were described by Sequeira and Panton (*Brit. J. Derm.* (1921) 33, 291) under the term of "lymphoblastic erythroderma". In these cases the skin presents a peculiar, dull, red-brick colour and a definite thickening to palpation, part at least of which is the result of cutaneous œdema. There is usually generalized enlargement of the lymphatic glands and very marked irritation. The blood-counts vary immensely, even from week to week, and one week there may be a small leucocytosis whilst in the following week the leucocytosis may be considerable. Almost invariably there is considerable relative lymphocytosis. I saw one of Sequeira's original cases in 1921 and have only seen two or three such clinical pictures since. The present case appears to me to present the clinical picture which I have tried to describe.

Dr. Brian Russell: I have a woman under observation with an identical skin appearance and a white cell count of 24,000 per c.mm., 83% of which are lymphocytes.

Dr. C. H. Whittle: The point which has interested me most is whether any of these leukæmic erythrodermia cases recover. Once the diagnosis of leukæmia is made the death warrant is more or less signed. Yet on going through the reports in the American literature I find that this is not necessarily true, and I can recall one case (Fraser, J. F., *Arch. Derm. Syph.* (1943) 48, 42), clinically lymphatic leukæmia, with a leucocytosis as high as 100,000 per c.mm., 80% lymphocytes (somewhat resembling monocytes) which showed complete recovery following X-ray therapy for at least two years. Sternal marrow was negative.

On the other hand a careful study of a case of erythrodermia of seven years' history, clinically leukæmic, by Hitch, J. C., and Smith, Dudley C. (1937) *Arch. Derm. Syph.*, 36, 1, with counts of 30,000 to 40,000 leucocytes, 80% to 90% lymphocytes, showed no histological evidence at autopsy of leukæmia. Either leukæmia is a disease from which recovery is possible, though infrequent, or many of these erythrodermia cases are not true leukæmias (Hugh-Jones, P., and Whittle, C. H., *Proc. R. Soc. Med.* (1943) 36, 612). The subsequent history of such cases with histological study is vital for their proper assessment.

mation with œdema and purulent infiltration in papillary layer of corium. Gram-stains show no bacteria. There are no special features suggesting virus infection.

Drugs.—No bromides or *iodides* have been given. The following were used by the home doctor:

(1) Belladonna—for a day or two only, 23.9.46.

(2) Cough mixture from 23.9.46 to 14.10.46

containing Vin. Ipecac.
Tr. Scillæ
Syr. Tamarinth
Syr. Rhœados
Syr. Ribis nig.

(3) Glyc. of ichthyol for balanitis, 27.9.46.

(4) Plain tulle-gras for the burn, followed by penicillin cream. Tulle-gras contains 1% balsam of Peru which itself contains benzyl benzoate and other similar substances.

Wassermann negative.

Mantoux 1 : 1,000 negative, human and bovine.

Comment.—Virus disease or drug eruption, ? ipecacuanha.

Dr. J. E. M. Wigley: I would suggest that it might be simpler to give this child small doses of whatever drugs are found to have been present in the cough mixture, one at a time. The result should prove most helpful, but I still think the clinical appearances of the eruption are strongly in favour of it being a bromide one.

Dr. F. Parkes Weber: Much depends on the course of this eruption. If the eruption now disappears completely without any special treatment, I think that one must regard it as having been a bromide eruption. But to make quite sure of this, the child (as suggested) might be given a little bromide cautiously to see if the eruption returns and if the child has an idiosyncrasy towards bromide. With care it would not do the child any harm.

Dr. Whittle: I questioned the mother very carefully and the doctor three times and got the whole list (given above) with the various ingredients of the cough mixture. Bromides were conspicuous by their absence.

POSTSCRIPT (23.12.46).—A course of bromide by mouth for a week followed by a course of iodide by mouth has *not* resulted in any further outbreak of the eruption.—C. H. W.

Lupus Vulgaris and Tuberculides of Face.—BERNARD GREEN, M.R.C.S., L.R.C.P.

Mrs. D. J. S., aged 63.

This patient first came under my care in September 1942, with a patch of lupus vulgaris affecting the side of the left cheek and the lobe of the left ear. I treated this in various ways, including acid nitrate of mercury and the disease was kept under control. In February 1946, with the advent of calciferol, I gave her high potency ostelin. This she continued to take for six months and the improvement, as you have seen, is dramatic. To-day there is little, if any, activity to be seen. In August 1946, whilst still taking calciferol, she developed a papular eruption on her face, mainly affecting the cheeks, forehead, chin and side of the nose. This I treated by exposure to ultraviolet light once a week, and some of the lesions have resolved, leaving depressed scars.

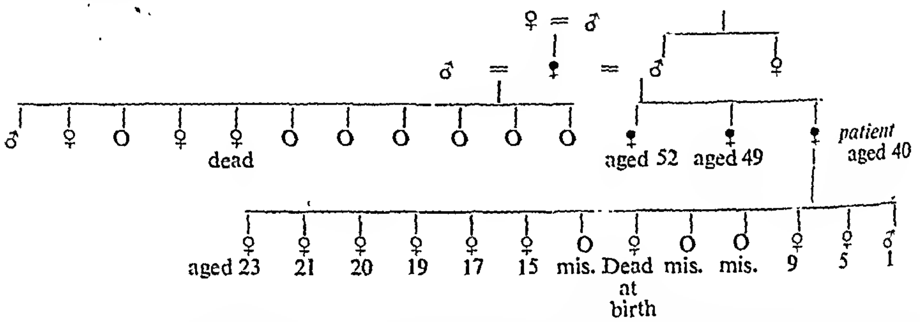
A skiagram of the chest revealed nothing abnormal. E.S.R. and blood-count showed no abnormality and a Mantoux test 1 : 10,000 is positive.

I show this case because I feel it is of some interest in view of the fact that whilst she was on calciferol treatment and the patch of lupus vulgaris was disappearing she developed these tuberculides. Whilst on calciferol treatment she felt depressed, heavy as though carrying a ton weight, had tachycardia and indigestion. All these symptoms have disappeared since stopping the calciferol treatment.

There has not been much change since puberty, but she noted some improvement in the condition after the first child was born and after each subsequent pregnancy. Her menstrual periods have been normal. She has nine children alive and well. She feels the cold but is not grossly myxœdematous in appearance.

Vitamin A.—Vitamin A in plasma 74 units (low normal); carotene in plasma 66 units (subnormal).

Family history.—Her mother and her only two sisters also show the same condition. None of her children do, even those, 6 in all, who have reached and passed puberty.



Dr. Whittle: I find difficulty in classifying this condition. The lesions include grouped comedones, but not such as are described by Thin, G. (1888) *Lancet* (ii), 712, Crocker, H. Radcliffe (1888) *Lancet* (ii), 813, and Wetherell and Sympson (1889) *Lancet* (i), 169. The skin is generally thick and abnormally dry. I should be grateful for suggestions.

Dr. F. Parkes Weber: Dr. Whittle has certainly proved his point, namely, that this is a form of family ectodermal dysplasia, although not so very many members of the family suffer from it. The hard follicular plugs (especially on the legs) constitute a striking feature, and I fancy that the condition is really not extremely uncommon. I would like to call it "a familial hyperplastic follicular dermatosis".

Dr. Whittle: I thank Dr. Parkes Weber for his suggestion. I will bear the title in mind.

? Kaposi's Varicelliform Eruption.—C. H. WHITTLE, M.D.

P. S., a boy, aged 1½ years.

History of an eruption starting about 30.9.46 on the left leg about a week after a burn, with blistering, of the left knee. The lesions increased in number and size and new ones appeared on the right leg, and a few small ones on the face. When first seen by me, 14.10.46, he presented large pyodermatous deep-red, heaped-up granulomata varying in size up to 2 cm. diameter on front and sides of legs chiefly below the knee. They grew larger—up to 3 to 4 cm. diameter—and the child was admitted to hospital for investigation.

Course.—His general health has been excellent throughout and his temperature never above 99°. The lesions have gradually subsided and there are now left the bluish-brown healing, or healed, areas visible on both legs. At one stage a few pock-like lesions were coming up about 8 mm. diameter, very reminiscent of smallpox pustules, with umbilication, but mostly the lesions were heaped pustular granulomata.

Bacteriology.—No organisms have been seen in, or grown from, the pus at any stage on repeated trials. Aerobic and anaerobic cultures have been put up, all sterile.

Animal inoculation.—Professor S. P. Bedson has kindly inoculated fluid from the pustules removed by sterile pipette before they were broken. Inoculations were made into mice intracerebrally, and guinea-pigs intradermally, with passage in the latter, but no virus of herpes or other type has been demonstrated.

Biopsy of pock-like lesion (section shown).—Non-specific granulomatous inflammation with œdema and purulent infiltration in papillary layer of corium. Gram-stains show no bacteria. There are no special features suggesting virus infection.

Drugs.—No bromides or *iodides* have been given. The following were used by the home doctor:

(1) Belladonna—for a day or two only, 23.9.46.

(2) Cough mixture from 23.9.46 to 14.10.46

containing Vin. Ipecac.
Tr. Scillæ
Syr. Tamarinth
Syr. Rhœados
Syr. Ribis nig.

(3) Glyc. of ichthyol for balanitis, 27.9.46.

(4) Plain tulle-gras for the burn, followed by penicillin cream. Tulle-gras contains 1% balsam of Peru which itself contains benzyl benzoate and other similar substances.

Wassermann negative.

Mantoux 1 : 1,000 negative, human and bovine.

Comment.—Virus disease or drug eruption, ? ipecacuanha.

Dr. J. E. M. Wigley: I would suggest that it might be simpler to give this child small doses of whatever drugs are found to have been present in the cough mixture, one at a time. The result should prove most helpful, but I still think the clinical appearances of the eruption are strongly in favour of it being a bromide one.

Dr. F. Parkes Weber: Much depends on the course of this eruption. If the eruption now disappears completely without any special treatment, I think that one must regard it as having been a bromide eruption. But to make quite sure of this, the child (as suggested) might be given a little bromide cautiously to see if the eruption returns and if the child has an idiosyncrasy towards bromide. With care it would not do the child any harm.

Dr. Whittle: I questioned the mother very carefully and the doctor three times and got the whole list (given above) with the various ingredients of the cough mixture. Bromides were conspicuous by their absence.

POSTSCRIPT (23.12.46).—A course of bromide by mouth for a week followed by a course of iodide by mouth has *not* resulted in any further outbreak of the eruption.—C. H. W.

Lupus Vulgaris and Tuberculides of Face.—BERNARD GREEN, M.R.C.S., L.R.C.P.

Mrs. D. J. S., aged 63.

This patient first came under my care in September 1942, with a patch of lupus vulgaris affecting the side of the left cheek and the lobe of the left ear. I treated this in various ways, including acid nitrate of mercury and the disease was kept under control. In February 1946, with the advent of calciferol, I gave her high potency ostelin. This she continued to take for six months and the improvement, as you have seen, is dramatic. To-day there is little, if any, activity to be seen. In August 1946, whilst still taking calciferol, she developed a papular eruption on her face, mainly affecting the cheeks, forehead, chin and side of the nose. This I treated by exposure to ultraviolet light once a week, and some of the lesions have resolved, leaving depressed scars.

A skiagram of the chest revealed nothing abnormal. E.S.R. and blood-count showed no abnormality and a Mantoux test 1 : 10,000 is positive.

I show this case because I feel it is of some interest in view of the fact that whilst she was on calciferol treatment and the patch of lupus vulgaris was disappearing she developed these tuberculides. Whilst on calciferol treatment she felt depressed, heavy as though carrying a ton weight, had tachycardia and indigestion. All these symptoms have disappeared since stopping the calciferol treatment.

Cutaneous Papillomatosis.—R. M. B. MacKenna, M.D., and Brian Russell, M.D.

Miss B. M., aged 50.

In May 1946 she complained of soreness and thickening of the skin in the right groin. This condition had been present in a much milder form for years previously. At the same time, she noticed spots on the calves which her doctor diagnosed as purpura.

In August 1946 she noticed many warty lesions on the limbs and in the axillæ. The condition in the right groin spread to the left side and to the anal and internatal regions.

Family history.—Nothing relevant discovered.

Past history.—She suffered from gastric neurosis in the 1914-18 war. For three years she has again suffered from dyspepsia and retrosternal pain after meals. She has been very strict with her diet, not taking any meat or vegetables for the last three years, her diet consisting only of eggs, when available, milk, and bread and butter, with occasional oranges.

On examination.—A well-nourished woman. No anæmia. No evidence of endocrine disturbance. Mild angular conjunctivitis. Scalp shows heavy *pityriasis*. Slight acne of front of chest and numerous de Morgan's spots. Numerous lesions resembling common warts on hands, forearms, and axillæ, some with brownish pigmentary changes, particularly in their bases which are infiltrated and raised in some lesions. In the groin flexures, particularly on the right side. there is a slate-brown verrucose and sodden condition of the skin: also in the internatal region and perianal region, and involving the gluteal fold, with numerous satellite warty lesions around, varying from pinhead size upwards. There is a similar condition involving the navel. Purpura is not now apparent.

Investigations.—Biopsies from right forearm and internatal region both show papillomata. Vitamin C saturation test within normal limits. Wassermann reaction negative. Scraping from pubic lesions showed no fungi and culture yields no growth of fungi. Breasts: No evidence of neoplasm.

Gynæcologist's report.—No pelvic abnormality discovered.

Blood-count within normal limits.

Catheter specimen of urine.—Centrifugalized deposit W.B.C. less than 1 per 1/6 in. field; R.B.C. less than 1 per 1/6 in. field: hyaline casts less than 1 per 2/3 in. field. Gram-stained film: No organisms. Culture sterile.

X-ray.—Chest: No evidence of pulmonary disease. Stomach and duodenum normal. Follow through: No neoplasm demonstrated in the alimentary tract.

Sigmoidoscopy: Nothing abnormal detected.

Treatment.—Treatment has consisted of three doses of X-rays 80 r each to vulva, anal area, and armpits; vitamin supplements, and bland local applications.

Comments.—This patient appears to be in good health apart from her skin condition, and full clinical and radiographic examination does not reveal the presence of a neoplasm. The histology of the biopsies performed is not that of acanthosis nigricans, as there is no increase of pigment in the basal and dendritic cells of the epidermis and there are no areas of atrophy in the prickle-cell layer; it is rather that of simple papillomata.

H. Gougerot and A. Carteaud ("Year Book of Dermatology and Syphilology", 1932, p. 174) tabulate four forms of cutaneous papillomatosis and differentiate them from epidermodysplasia verruciformis, verrucæ planæ juveniles and morbus Darier. It is suggested that this case resembles the type "pigmentées verruqueuses" of Gougerot, Clara and Bonnin. The patient is also a seborrhœic subject.

Dr. F. Parkes Weber: I think the condition of the umbilicus is of great importance in regard to diagnosis. In my view the involvement of the umbilical region does really suggest acanthosis nigricans.

[*December* 19, 1946]

Erythematous Initial Tuberculide

By W. J. Hohmann, M.D., Groningen, Holland

During the occupation in Holland conditions of health and nutrition were greatly depressed, though they were not so bad in the north-east of Holland, where I was living and made my observations, as they were in other parts of the country. In 1942 a case was sent to me by a practitioner who stated that he had never seen this peculiar type of eruption before and I, too, had to admit that I had not seen it before. The patient showed a rash consisting of erythematous flat papules with pin-point small vesicles here and there, located on the neck and the extensor sides of the forearms, accompanied by erythema nodosum and conjunctivitis phlyctenulosa. It was impossible to make a diagnosis but an atypical form of tuberculide was presumed and radiological changes in the lung were found. The Pirquet tuberculin test was bullous. Though the diagnosis "atypical tuberculide" did not satisfy me, it was impossible to classify the dermatosis under one of the existing forms of tuberculides.

Altogether I saw six of these cases, all showing radiological changes in the lungs with a high sensitivity of tuberculin. In Urbach's book on Allergy, I came across the publications of Christjansen, Geissler, Kojima, Keiser, on tuberculin exanthemata. They believed that when an incipient tuberculosis passes from the first phase of Ranke into the second, at the moment when tuberculin sensitivity is at its highest, the application of tuberculin can give rise to exanthematous reactions. The skin eruption I saw might possibly also indicate this moment. These six patients stated that they had never had tuberculosis, but it was impossible for me to exclude an earlier infection with certainty.

From these six patients I came to the tentative conclusion that this dermatosis (1) was not just an atypical tuberculide, but that it must be a *very typical* one; (2) had a transient character (the rash disappeared in a few days to two to three weeks); (3) in some cases had a slight resemblance to erythema multiforme Hebræ but was distinctly different in its evolution; (4) was accompanied by a high sensitivity to tuberculin; (5) was, most likely, connected with tuberculosis; (6) *possibly* indicated a primary infection.

In 1945 I saw two nurses who had been tested for Pirquet and Mantoux reactions with negative results a few months previously; and the X-ray examination was also negative. Now they showed the same skin rash, the sensitivity to tuberculin was very high, and the X-ray showed changes in the lungs, most probably a primary tuberculosis. Later on the diagnosis of pulmonary tuberculosis was easily confirmed.

The previous medical examination excluded in these two nurses an earlier tuberculous infection.

Therefore my conclusion became more definite, and No. 6 (above) became: *most likely* indicated a primary infection.

In the earlier literature on skin rash in tuberculosis, Uffenheimer, Kundratitz and von Moritz record a few cases of children with a primary tuberculous infection developing a transitory skin rash, in one case more or less similar to erythema multiforme Hebræ.

In the middle of 1945 a patient came to hospital with pneumonia and was given sulphathiazole and a fairly extensive rash appeared. When I examined the eruption in the light of this recent experience, I said at once that it must be primary tuberculosis. In ten days' time the rash disappeared and the temperature came down, but two weeks later the patient developed fever again, and she died of meningitis tuberculosa. Post-mortem examination showed a primary focus in the lung.

It was noted that in this case the high sensitivity to tuberculin decreased in a very short time to just slightly positive, which might be an indication that danger is ahead. I was therefore certain that the dermatosis indicates a primary infection.

Bloch[1] published a case which must be similar to my cases, under the title: "Atypical Tuberculide Resembling Erythema Multiforme." As he saw only one case, he could not connect it with primary tuberculosis.

In Darier's "Précis de Dermatologie", I found one interesting sentence: "Si l'on se trouve en présence d'un de ces cas, que les travaux du Prof. Landouzy et de ces élèves ont montrés d'être assez fréquents, où l'érythème polymorphe se développe à la faveur de la tuberculose, il y a lieu de prescrire aux convalescents une hygiène appropriée et de les soumettre à une surveillance prolongée."

As in those days erythema nodosum was included with erythema multiforme, I cannot make out to what symptoms Landouzy referred. In the French bibliography after the war, I also found a few cases. In the Swedish bibliography I saw the report of a case that ended fatally and post-mortem examination was performed. A primary focus in the lung was found (the case was published for a different reason).

Assuming that an idiopathic form of erythema multiforme Hebræ actually exists, I suggest that where a disease of known ætiology but resembling the skin eruption of that disease is described, it should be named in such a manner as to make evident the more marked characteristics.

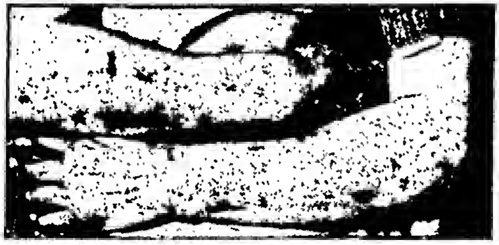


FIG 1.—Woman aged 60. Erythematous initial tuberculide.

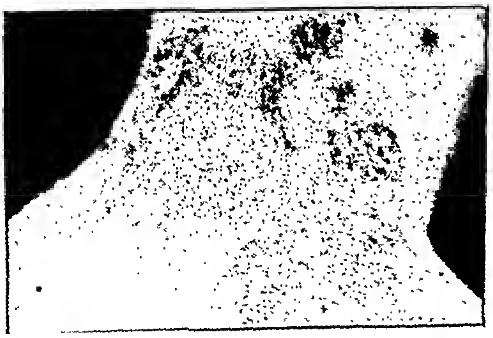

FIG. 2.—Woman aged 30. Erythematous initial tuberculide.

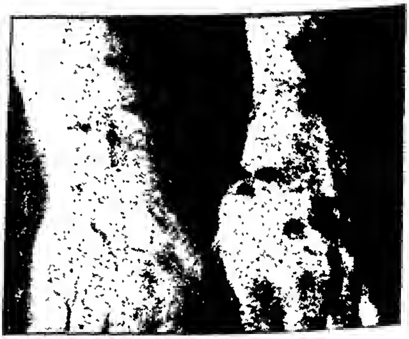

FIG. 3.—Woman aged 30; Erythematous initial tuberculide.

This dermatosis has some or all of the following characteristics:

(1) Rose-coloured to more livid patches, only slightly raised above the surface of the skin, with very little superficial infiltration; showing so little inflammatory œdema that the natural lines of the skin remain intact or are even more exaggerated; capricious of contour with a gradual change to the normal aspect of the skin and disappearing completely with diascopy; healing in a few days' to a few weeks' time whereby the efflorescence gets uniformly paler, and leaves no scars or pigmentation (*see* fig. 1).

---

[1] Bloch, B., *Schweiz. med. Wschr.* (1923) 53, 639.

(2) Pin-point, minute vesicles, on a red surface, rarely becoming confluent so as to form a bulla; showing a yellowish-brown transparent aspect and healing with fine scaling (*see* fig. 2).

(3) Spherical papules, pea-size, with a smooth glittering surface and flattened top, yellow to reddish-brown, showing practically no infiltration by diascopy and healing without scars.

(4) Nummular, flat, slightly elevated, red, œdematous papules without visible skin lines, and without deep-seated infiltration. When healing the rash gets paler and disappears. Very rarely a larger area of the skin may have this aspect (*see* fig. 3).

(5) Rounded or oval, bright red, tender nodes, later changing into dusky lividity losing their tenderness in this phase. The nodes undergo re-absorption, leaving behind a bluish hæmorrhagic discoloration which may change colour from blue to green and then to yellow before it disappears completely (erythema nodosum).

(6) The rash usually selects the extensor sides of the extremities, the neck and in some cases the face, *and is accompanied by some of the following symptoms*:

(*a*) A very high tuberculin sensitivity characteristic of the disease and essential for the diagnosis.
(*b*) Fever.
(*c*) General malaise.
(*d*) Enlarged hilus, or infiltration in the lung.
(*e*) Pleuritis.
(*f*) Conjunctivitis phlyctenulosa, or irritatio bulbi.

Furthermore

(1) Is transitory and does not recur.
(2) The skin eruption is harmless but prognosis must be guarded because
(3) it points with certainty to a primary tuberculous infection.
(4) The condition occurs at all ages.

I would suggest that this syndrome be called *tuberculosis initialis cutis erythematosæ* or *erythematous initial tuberculide*.

Dr. W. N. Goldsmith: Will Dr. Hohmann tell us more about the technique and results of the tuberculin tests?

Dr. Hohmann: I made a dilution of one to ten, one to one hundred and so on. I found a positive reaction even with a dilution of one to one hundred million. The reaction was adequate, that is to say, it was proportionate to the dilution employed. This is important, as in dermatoses resembling erythema multiforme Hebræ it is necessary to exclude an isomorphic Köbner effect, so common in this disease. Therefore it is always necessary to have controls.

Dr. Goldsmith: What was the subsequent history of most of these cases?

Dr. Hohmann: Some developed tuberculosis and some healed up; one case died. I do not think a certain prognosis is coupled to this eruption, it only makes possible the early diagnosis of primary tuberculosis about two months after the infection. On the other hand if a sudden decrease of the sensitivity to tuberculin in a short time is observed, this might be regarded as a fatal indication. All the cases of which I have been speaking had a very high sedimentation rate.

Dr. H. Corsi: We should all like to compliment Dr. Hohmann on his technique of presentation. He has not only spoken to us in admirable English, but has printed the words for us on the lantern screen. The combination of the spoken and the visible word has brought this subject very clearly before us.

The President: We have to thank Dr. Hohmann for a most interesting discourse—a subject excellently presented and certainly most stimulating of thought. We ask him to take back with him to Holland not only our thanks to himself but also our compliments to our Dutch colleagues.

very short time to just slightly positive, which might be an indication that danger is ahead. I was therefore certain that the dermatosis indicates a primary infection.

Bloch[1] published a case which must be similar to my cases, under the title: "Atypical Tuberculide Resembling Erythema Multiforme." As he saw only one case, he could not connect it with primary tuberculosis.

In Darier's "Précis de Dermatologie", I found one interesting sentence: "Si l'on se trouve en présence d'un de ces cas, que les travaux du Prof. Landouzy et de ces élèves ont montrés d'être assez fréquents, où l'érythème polymorphe se développe à la faveur de la tuberculose, il y a lieu de prescrire aux convalescents une hygiène appropriée et de les soumettre à une surveillance prolongée."

As in those days erythema nodosum was included with erythema multiforme, I cannot make out to what symptoms Landouzy referred. In the French bibliography after the war, I also found a few cases. In the Swedish bibliography I saw the report of a case that ended fatally and post-mortem examination was performed. A primary focus in the lung was found (the case was published for a different reason).

Assuming that an idiopathic form of erythema multiforme Hebræ actually exists, I suggest that where a disease of known ætiology but resembling the skin eruption of that disease is described, it should be named in such a manner as to make evident the more marked characteristics.

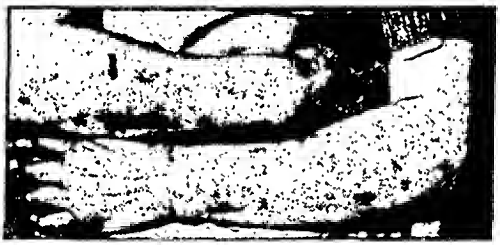

FIG 1.—Woman aged 60. Erythematous initial tuberculide.

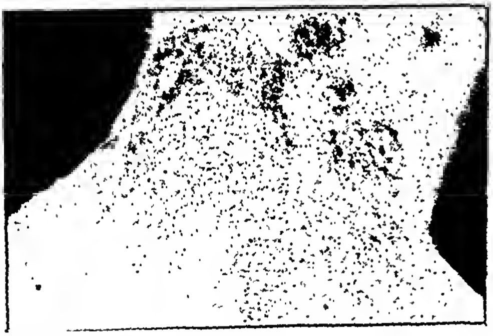

FIG. 2.—Woman aged 30. Erythematous initial tuberculide.

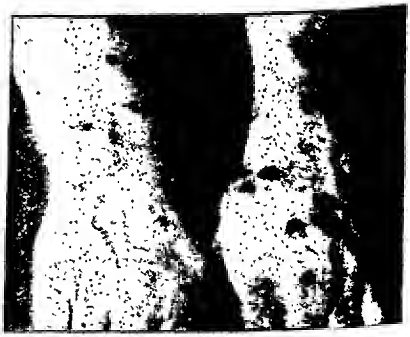

FIG. 3.—Woman aged 30. Erythematous initial tuberculide.

This dermatosis has some or all of the following characteristics:

(1) Rose-coloured to more livid patches, only slightly raised above the surface of the skin, with very little superficial infiltration; showing so little inflammatory œdema that the natural lines of the skin remain intact or are even more exaggerated; capricious of contour with a gradual change to the normal aspect of the skin and disappearing completely with diascopy; healing in a few days' to a few weeks' time whereby the efflorescence gets uniformly paler, and leaves no scars or pigmentation (*see* fig. 1).

[1] Bloch, B., *Schweiz. med. Wschr.* (1923) 53, 639.

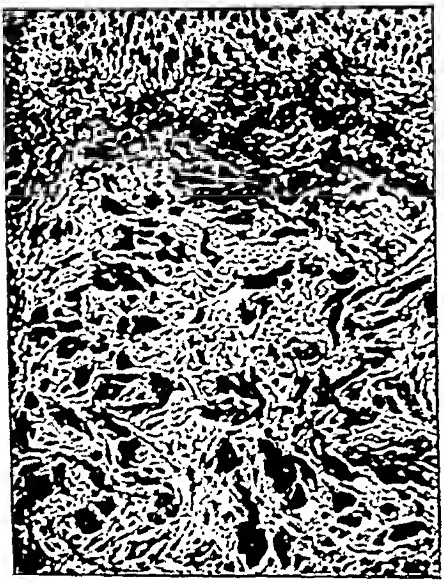

FIG. 3.—Forehead. Collagen bundles broken up and displaced by strands, fibrinoid and granular masses, stained yellow with van Gieson. Narrow subepidermal strip in this and the previous picture almost unchanged. × 170.

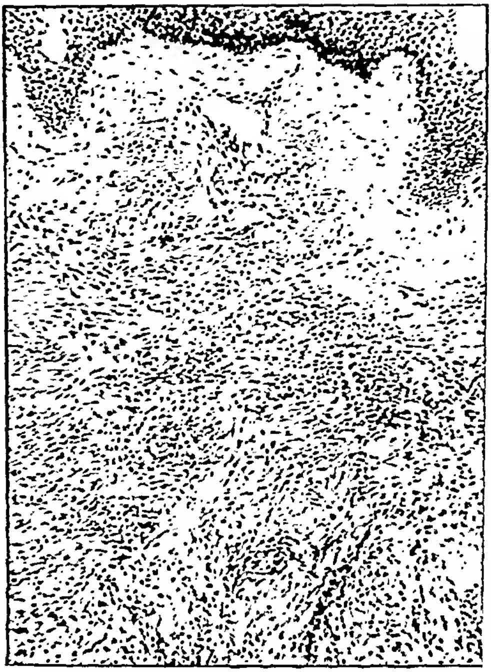

FIG. 4.—Forehead. Fairly dense cellular infiltrate, arranged diffusely or in short strands. A small amount of mucin in the right lower corner. × 80.

Dr. Brian Russell; The facial lesion seemed to me almost cartilaginous in texture, not œdematous. In the lesions on the arms there were a large number of discrete, dome-shaped papules, at the upper limit of the confluent infiltrated plaques.

It is interesting to note the lack of response to thyroid therapy. Pillsbury and Stokes (*Arch. Derm. Syph., Chicago* (1931) 24, 255) in their report on a case of the plaque type, state that this form arising in the pretibial region is always associated with exophthalmic goitre whereas the tuberose form, in which there is diffuse infiltration of the face, may, but often does not, react to thyroid treatment. This patient falls in the latter tuberose group.

Nodules in Abdominal Wall for Diagnosis ? Fibrosarcoma (Darier and Ferrand).—

A. C. ROXBURGH, M.D.

Mrs. M., aged 36. Complains of lumps in abdominal wall. Six years ago noticed painless lump in skin over left lower rib cartilages. Three to four years ago similar lumps right side of abdomen to right of operation scar. The lumps have increased in size and number. They are painless but irritate slightly. Patient is otherwise well. Periods regular, no pain, one child aged 7 years. No miscarriages.

Operations.—1923: Appendicitis and abscess. Tube in wound. Three months in hospital. 1924: Intestinal obstruction due to adhesions from previous operation. Scar right side, medial to other. 1937: "Twisted ovary" or "cyst of fallopian tube". Scar left side. Pleurisy March 1944, right base, with effusion. Similar attack December 1944 but no effusion. Subsequent X-rays show no abnormality in chest. Sputum, no tubercle bacilli December 1944.

Myxœdema Circumscriptum.—W. FREUDENTHAL, M.D.

Histological demonstration of Dr. Brian Russell's Case for Diagnosis, shown on October 17, 1946, *Proc. R. Soc. Med.*, **40,** 12 (*see* fig. 1).

For diagnostic purposes I excised a strip of tissue from the waxy plaque on the forehead and another from the border of the confluent area on the left arm including some outlying papules.

In both biopsies, particularly in the first, the cutis is considerably thickened and is extensively changed in its upper half, except for an almost normal narrow subepidermal strip. The collagen bundles are separated by an œdema, broken up and displaced by strands, fibrinoid and granular masses, stained yellow with van Gieson (figs. 2 and 3). In these areas there is a fairly dense infiltrate consisting of cells with pale or darkish oval nuclei which are arranged diffusely or in short, irregular strands (fig. 4).

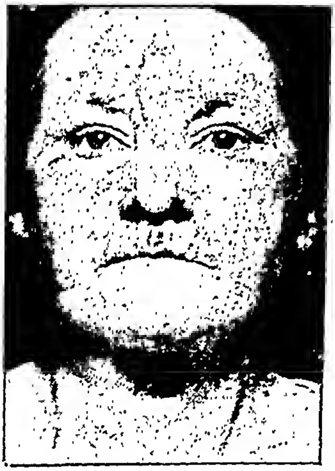

FIG. 1.—Myxœdema circumscriptum.

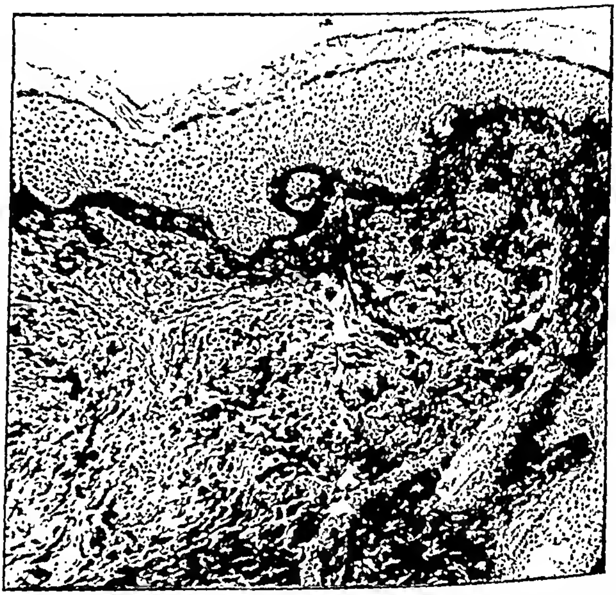

FIG. 2.—Arm. Across the border of the lesion. Connective tissue changes in the left half of the picture. van Gieson. × 70.

When stained with thionin or toluidin-blue large masses of mucin are seen, stained pink metachromatically. In the lesion from the arm mucin is found throughout the areas of altered connective tissue; in the lesion from the forehead it is mainly seen in the lower half of these areas whilst the upper half is free or shows only very little.

The presence of mucin confirms that this case belongs to the myxœdema group as I had suggested, on clinical grounds, when Dr. Russell demonstrated his case for diagnosis at the October meeting of this Section.

Clinically, the primary lesion is a dome-shaped papule which has a tendency to aggregate and later to coalesce, thus forming large sheet-like areas on the arms and hands. We are familiar with this development in other forms of circumscribed myxœdema, e.g. myxœdema moniliforme. In the waxy plaque on the face the papules can be seen only with difficulty, but they can still be felt. I have not seen a plaque like this in circumscribed myxœdema, but feel reminded of the facial changes occurring in generalized myxœdema.

Malling at my suggestion have been followed by some reduction in the redness and hardness of the lesions.

Dr. F. Parkes Weber: I should like to support a suggestion—actually made to me by Dr. Goldsmith—that these lesions are of the nature of keloid. But what is the nature of keloid? Ordinary keloid is, I suggest, a chronic *idiosyncratic* reaction towards some substance which is normally produced in connexion with the healing of wounds. The reason why most people do not develop keloid after wounds is, I suggest, that they lack the special idiosyncrasy. There may be, moreover, a factor in connexion with the healing of wounds which in some cases causes the production of a great deal more of this hypothetical substance than in other cases. I think we can go a stage further. What is probably very much rarer is the local production of this hypothetical keloid-causing substance, in connexion, not with wounds, but with various kinds of irritation, such, for example, as the constant rubbing of clothes about the waist. This suggestion would explain the extreme rarity of keloid without wounds of any kind. I suggest that the hypothetical keloid-causing substance is formed not only in connexion with actual wounds but occasionally (though extremely rarely) with other irritations of the skin. That is what I suggest has happened in the present case, and that would explain why the appearance of the main (active) lesions is that of a rosy coloured fairly active keloid. If I am correct, the probability is that ultimately, when the patient grows considerably older, the lesions will become paler, the rosy colour will be lost, and the keloid growth will shrivel. Is it worth while on this theory to try the effects of local X-ray therapy, such as, I know, occasionally produces the cure of ordinary keloids?

Dr. W. N. Goldsmith: It is true that I got the clinical impression of keloid before I knew anything of the histological structure; but there is, of course, the difficulty to which Dr. Parkes Weber has alluded, of the keloid arising where there is no scar. If, as Dr. Parkes Weber suggests, keloids are the result of an idiosyncratic reaction to a substance normally produced by healing wounds, one wonders why in this case there has been no such reaction in connexion with extensive scars elsewhere.

Dr. H. Corsi: The lesion does not appear to me in the least like a keloid: to say in words how we recognize physical signs, especially visual signs, is not easy; but in the main I would say that this lesion does not lie as near the surface as a keloid. A keloid is situated immediately under the epidermis, but this lesion lies deeper, a fact which is appreciable at the margins. There the edge of the tumour is palpable as it lies well below the normal skin. The tumour is, in fact, subcutaneous, but by extension towards the surface it has invaded and caused ulceration of the skin, and by extension deeply it has become attached to the costal cartilages.

I must disagree also with Dr. Parkes Weber's statement that spontaneous keloids, i.e. keloids not associated with any visible scar, are uncommon. I have seen a great number, particularly on the sternal region in women, a condition sometimes described as Alibert's disease.

Dr. Parkes Weber: I should like to point out that in my remarks I was referring only to the later lesions, those not connected with the operation.

Dr. A. C. Roxburgh: This condition does not look to me in the least like keloid. The lesions are not pink but brown, and not on the sites of the scars. On the left there is no scar near the lesion. This is some sort of fibrotic new growth, but not keloid.

Polymorphic Light Eruption.—F. Ray Bettley, M.D.

A. L., a male, aged 17. For fourteen years this patient has been subject to an eruption on the face, particularly in its upper part. The attacks occur only in summer, between the months of May and September and last some three or four weeks with incomplete remissions of about six weeks. Attacks do not appear to be related to particular exposures to sun, wind or other provoking cause. The eruption is itchy and consists of some vesicles, with scaly patches.

His general health has always been good; there is no family history of any skin disorder.

This year, for the first time, the eruption has lasted until the present time of year.

On examination.—There is a patchy scaly excoriated eruption symmetrically situated on the forehead, nose, and upper parts of the cheeks. No other abnormality found.

On examination: Brown, very hard, nodular masses in skin of abdominal wall over an area 5 by 2 in. to right of operation scars at outer side of right rectus abdominis mainly below level of the umbilicus. Similar but more massive area with depressed scaly centre in mid-clavicular line over the lower left costal cartilages, 2½ by 2½ in. This is seated upon and adherent to an underlying infiltrated area forming a somewhat raised cushion extending about ½ in. all round the surface lesion. Individual nodules are ¼ to ½ in. in diameter. The surface of the younger lesions is unaltered, that of the older ones is scaly or crusty (*see* fig.). They never break down or discharge and are unaffected by her menstrual periods. No viscus felt, no enlarged lymph glands.

Pathological examinations (November 1946).—W.R. and Kahn negative.

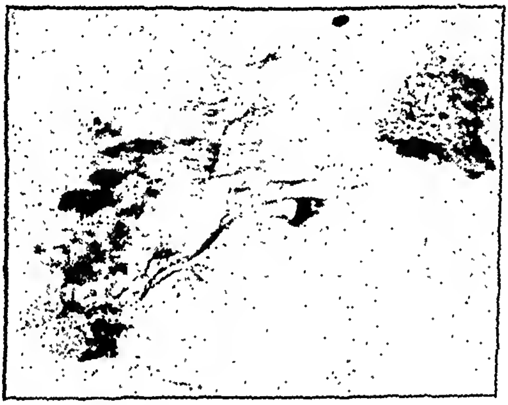

FIG. 1.—Dr. A. C. Roxburgh's case of fibrosarcoma of abdominal wall.

Biopsy (November 18, 1946).—From young nodule upper right abdomen (section shown).

Report (Dr. Muende).—The collagen in the mid-corium is very dense and numerous fibrocytes and groups of lymphoid cells can be found between the dense collagen bundles. The section shows no special pathological characteristics beyond these changes.

On December 6, 1946, the patient was put on a potassium iodide and mercury mixture t.d.s. as a therapeutic test and to-day shows some slight improvement. Probably another biopsy will have to be done from an older lesion.

Dr. Barber has suggested that the condition may be a type of the fibrosarcoma described by Darier and Ferrand (*Ann. Derm. Syph., Paris*, 1924, **5**, 545).

POSTSCRIPT (December 30, 1946).—A recent paper by O. G. Costa (*Arch. Derm. Syph., Chicago* (1946) **54**, 432) refers to one by G. W. Binkley (*Arch. Derm. Syph., Chicago* (1939) **40**, 578) which shows two photographs of lesions very like those in this case, one on the left side of the abdomen and one in the right supraclavicular fossa. Binkley draws attention to the tendency of dermatofibrosarcoma to occur on sites corresponding to the embryonic mammary ridge which would apply to both the lesions in this case. The sections reproduced in these papers seem to me to resemble that from this case.

POSTSCRIPT (March 14, 1947).—A further biopsy (10.1.47) taken from an old lesion in the centre of the mass on the right side of the abdomen was reported on by both Dr. Muende and Dr. Freudenthal as fibrosarcoma. A curious feature is that three intravenous injections of N.A.B. given by Dr. Vincent Bates of West

Malling at my suggestion have been followed by some reduction in the redness and hardness of the lesions.

Dr. F. Parkes Weber: I should like to support a suggestion—actually made to me by Dr. Goldsmith—that these lesions are of the nature of keloid. But what is the nature of keloid? Ordinary keloid is, I suggest, a chronic *idiosyncratic* reaction towards some substance which is normally produced in connexion with the healing of wounds. The reason why most people do not develop keloid after wounds is, I suggest, that they lack the special idiosyncrasy. There may be, moreover, a factor in connexion with the healing of wounds which in some cases causes the production of a great deal more of this hypothetical substance than in other cases. I think we can go a stage further. What is probably very much rarer is the local production of this hypothetical keloid-causing substance, in connexion, not with wounds, but with various kinds of irritation, such, for example, as the constant rubbing of clothes about the waist. This suggestion would explain the extreme rarity of keloid without wounds of any kind. I suggest that the hypothetical keloid-causing substance is formed not only in connexion with actual wounds but occasionally (though extremely rarely) with other irritations of the skin. That is what I suggest has happened in the present case, and that would explain why the appearance of the main (active) lesions is that of a rosy coloured fairly active keloid. If I am correct, the probability is that ultimately, when the patient grows considerably older, the lesions will become paler, the rosy colour will be lost, and the keloid growth will shrivel. Is it worth while on this theory to try the effects of local X-ray therapy, such as, I know, occasionally produces the cure of ordinary keloids?

Dr. W. N. Goldsmith: It is true that I got the clinical impression of keloid before I knew anything of the histological structure; but there is, of course, the difficulty to which Dr. Parkes Weber has alluded, of the keloid arising where there is no scar. If, as Dr. Parkes Weber suggests, keloids are the result of an idiosyncratic reaction to a substance normally produced by healing wounds, one wonders why in this case there has been no such reaction in connexion with extensive scars elsewhere.

Dr. H. Corsi: The lesion does not appear to me in the least like a keloid: to say in words how we recognize physical signs, especially visual signs, is not easy; but in the main I would say that this lesion does not lie as near the surface as a keloid. A keloid is situated immediately under the epidermis, but this lesion lies deeper, a fact which is appreciable at the margins. There the edge of the tumour is palpable as it lies well below the normal skin. The tumour is, in fact, subcutaneous, but by extension towards the surface it has invaded and caused ulceration of the skin, and by extension deeply it has become attached to the costal cartilages.

I must disagree also with Dr. Parkes Weber's statement that spontaneous keloids, i.e. keloids not associated with any visible scar, are uncommon. I have seen a great number, particularly on the sternal region in women, a condition sometimes described as Alibert's disease.

Dr. Parkes Weber: I should like to point out that in my remarks I was referring only to the later lesions, those not connected with the operation.

Dr. A. C. Roxburgh: This condition does not look to me in the least like keloid. The lesions are not pink but brown, and not on the sites of the scars. On the left there is no scar near the lesion. This is some sort of fibrotic new growth, but not keloid.

Polymorphic Light Eruption.—F. Ray Bettley, M.D.

A. L., a male, aged 17. For fourteen years this patient has been subject to an eruption on the face, particularly in its upper part. The attacks occur only in summer, between the months of May and September and last some three or four weeks with incomplete remissions of about six weeks. Attacks do not appear to be related to particular exposures to sun, wind or other provoking cause. The eruption is itchy and consists of some vesicles, with scaly patches.

His general health has always been good; there is no family history of any skin disorder.

This year, for the first time, the eruption has lasted until the present time of year.

On examination.—There is a patchy scaly excoriated eruption symmetrically situated on the forehead, nose, and upper parts of the cheeks. No other abnormality found.

Investigations.—Coproporphyrins are present in the urine to the extent of 4 mg. per litre in the specimen quantitatively examined. The estimated porphyrin excretion in this patient is forty times the normal.

Serum proteins normal.

Reaction to a test dose of ultraviolet (mercury vapour) normal.

Normal reactions were also obtained to infra-red, visible red, and artificial white (electric filament lamp) light.

Treatment and progress.—No improvement while in hospital in a shaded part of the ward. No improvement resulted from the application of 10% tannic acid in an emulsified base, nor from a lotion of 5% quinine bihydrochloride.

Hyperkeratosis Follicularis et Parafollicularis in Cutem Penetrans (*Kyrle*[1]).—J. R. SIMPSON, M.B.

Miss A. W., aged 63. Housekeeper.

History.—Seven years ago multiple horny pimples first appeared on the backs of her fingers, hands and forearms, and soon spread to her legs, ankles and feet. Apart from their unsightliness, the only symptom has been a mild sensation of pricking in each lesion when it reaches full development; in her own words, "when they prick me, I pull them out".

She has suffered from a mild otitis externa for some years. Her general health has been good except that she is subject to bronchitis and had brachial neuritis in 1943 and again earlier this year.

There is no family history of any skin disease.

On examination.—On the back of the hands and of the proximal phalanges and on the forearms, knees, legs, ankles and the dorsa of the feet, there are multiple discrete lesions varying from 0·5 mm. to 4 mm. in diameter. They are small brownish-yellow, horny papules with a rough surface. Some, but not all, are related to hair follicles. The horny plugs can easily be shelled out, leaving smooth round pits, the bases of which are red, but do not bleed.

There are a few yellowish-brown macules interspersed with the above, chiefly about the ankles, but the patient states that these appeared independently and not on the sites of previous horny pimples.

Histology (Material taken from the leg).—There is hyperkeratosis and a dense, wide horny mass has pushed down the deeper layers of the epidermis to the level of the junction of the reticular and papillary parts of the corium. In the deepest part there is parakeratosis and the underlying granular layer is absent.

There is acanthosis on either side of and beneath the horny mass, but in one place the basal layer is absent and the prickle-cell layer is thin and invaded by a dilated blood-vessel, from which there has been some extravasation of erythrocytes.

The corium shows no pilosebaceous structures, but around the lesion there is a moderately dense infiltration of lymphocytes and fibroblasts. The vessels are dilated and show endothelial proliferation.

Treatment.—Vitamin A, 100,000 i.u. daily, orally for three months.

Since I last saw her, a month ago, there has been a striking regression of the lesions, which are smaller and less numerous.

Dr. W. J. Hohmann: I have seen several cases of vitamin A deficiency in Holland. In most of them I made estimations of the vitamin A of the blood serum and found very low values. It seemed to me that this condition was part of a vitamin A deficiency. My cases improved after administration of vitamin A, but it takes some time before improvement can be seen. I think that Kyrle's disease is not a separate entity, but is a part of a vitamin A deficiency.

Section of Anæsthetics

President—STANLEY ROWBOTHAM, M.D.

[*January* 3, 1947]

DISCUSSION: ANÆSTHESIA FOR ABDOMINO-PERINEAL OPERATIONS FOR CANCER OF THE RECTUM

Dr. Ronald Jarman: Exactly forty years ago W. Ernest Miles performed his first operation for cancer of the rectum, and it is this operation which bears his name. The first three operations for this condition did extremely well, but subsequent results varied. Experience, improvement of technique and team work have now reduced the mortality rate to less than 5%, which my experience of over 1,000 cases has proved. From 1907 to the present date the general technique has improved and with it the anæsthesia as the list shows. Spinal analgesia has replaced ether and chloroform, thus getting the maximum relaxation without the use of irritant vapours, nitrous oxide and oxygen being used to keep the patient asleep. The premedication has become more or less standardized, omnopon 1/3 grain and scopolamine 1/150 grain are given to the average adult one hour before the operation; this produces a somnolent state and facilitates the giving of nitrous oxide and oxygen.

The introduction of intravenous anæsthesia fifteen years ago has abolished all psychic shock, the patient being put to sleep in bed and conscious only of a slight prick in the arm and oblivious of all further manipulations. This form of anæsthesia is either maintained by nitrous oxide and oxygen or by the administration of more of the intravenous drug.

ANÆSTHESIA FOR ABDOMINO-PERINEAL EXCISION IN CANCER OF THE RECTUM.

January 7, 1907.

W. Ernest Miles did his first abdomino-perineal operation for cancer of the rectum, the anæsthetic being ether, using a Clover's inhaler.

	Premedication	Anæsthetic
1908	Atropine	Open ether
1910	,,	Chloroform and ether mixture, followed by chloroform
1912	Atropine and scopolamine	,, ,, ,, ,, ,, ,, ,,
1917	,, ,,	Open ether
1919	,, ,,	Stovaine. Spinal
1920	,, ,,	Gas and oxygen. Stovaine
1924	,, ,,	,, ,, ,, ,, Sacral block novocain 20 c.c. 2%
1927	,, ,,	,, ,, ,, ,, ,, ,, ,, 40 c.c. 1%
1929	,, ,,	Spinocaine. Gas and oxygen (Jarman)
1930	Omnopon and scopolamine	Gas and oxygen. Nupercaine 18 c.c. 1 in 1,000
1931	,, ,,	,, ,, ,, ,, ,, ,, 1 in 1,500

1946	Omnopon 1/3 gr. and scopolamine 1/150 gr.	Pentothal 10-20 c.c. 5% solution. Gas and oxygen. Nupercaine 12-15 c.c. 1 in 1,500 and ephedrine 1 gr.

As a result of these advances chest and abdominal complications are fewer.

The age-incidence of cancer of the rectum varies from 17 years to 82 years, the average being between 60 and 75 years.

Blood-pressure.—The routine charting of blood-pressures as well as respirations, pulse-rate and the various anæsthetic agents used, has assisted the anæsthetist to keep a watchful eye on the patient's condition. The giving of an injection of ephedrine 1 grain immediately before the spinal, following the work of Sebrecht of Bruges and his assistants, has prevented anxiety in the early stages of the operation. Dr. Frankis Evans' method of giving an adrenaline drip during the operation has definitely increased the safety margin. As long as the pulse-rate does not rise unduly, I do not use cardiac stimulants, no matter how low the blood-pressure falls. This fall is very marked when the patient is turned on to his side for the perineal part of the operation and sometimes cannot be recorded. If the pulse-rate starts to rise with this fall in blood-pressure, an intravenous drip is established immediately, and, if necessary, whilst this is being done, 2 or 3 c.c. of anacardone are given intramuscularly.

It is all important that the patient is well oxygenated during the operation and that special attention is paid to raising the percentage of the oxygen at this stage.

If a large number of anæsthetic charts of this particular operation are examined, it is noticed that if the pulse-pressure is low then the blood-pressure falls rapidly but if the pulse-pressure is medium or high, the fall is slow and very rarely calls for anxiety. Warmth and blood transfusions soon restore the blood-pressure to within reasonable limits.

Blood transfusions.—These are given immediately after the operation, followed by water and glucose 5% in sterile vacolitres. This measure is only adopted during the operation if the patient's condition demands it. There is no doubt that this part of the technique has gone a long way to make the operation safer.

Position of the operating table.—The new operating tables can be put into a Trendelenburg position of 60 degrees. This enables the surgeon to get the growth away and establish a new pelvic floor, making the perineal part of the operation quite a short procedure.

Routine treatment.—The patient should be admitted to hospital or nursing home for at least fourteen days prior to the operation. During this time the physician, surgeon, pathologist, dental surgeon and anæsthetist are able to examine the patient at their leisure and have a meeting about the case. The upper respiratory tract, especially the teeth, should be thoroughly investigated.

High colonic wash-outs are given over a period of days. The patient has large doses of sulphasuxadine by mouth to sterilize the bowel. Since this has been done, peritonitis following the operation has been eliminated. This has been ably described by Mr. Alan Hunt (*Proc. R. Soc. Med.*, 1946, **39**, 549).

The *physiotherapist* teaches the patient how to use all his muscles whilst lying in bed, especially how to breathe and use his abdominal muscles. It is during this period that the anæsthetist visits the patient so as to get to know him and at the same time to create confidence. It is most important to make the patient realize that he is the centre of the picture and that everything is being done for his comfort and safety.

Sigmoidoscopy.—The most important examination is that of a sigmoidoscopy and biopsy. Not only does it establish the diagnosis but it helps the anæsthetist to see how the patient reacts to the anæsthetic and the various drugs that he is given as well.

The day of the operation.—The patient has had a good night, assisted by medinal

10 grains and aspirin 10 grains. One hour before the operation he is given his injection of omnopon 1/3 grain and scopolamine 1/150 grain, followed by a small dose of 5% solution of pentothal just before he is moved to the theatre, where he has a spinal of light nupercaine 1 in 1,500 given, preceded by an injection of ephedrine, then surgical sleep is established by nitrous oxide and oxygen, assisted by a further injection of pentothal if required. The anæsthetist helps in getting the patient ready by emptying his bladder, adjusting shoulder rests and making sure that the table is in the right position.

The technique has enabled the surgeon to complete the straightforward case in under an hour and has also helped him to make the inoperable case operable, ensuring that all cases are in moderate comfort during their final days.

Sterilization of syringes and needles.—It is of interest at this point to describe how all the syringes and needles are kept sterile. They are always cleaned out with triple distilled water and then put into pure industrial spirit for at least an hour before the operation. Prior to use, they are again washed and kept covered in triple distilled water. This is important for all injections, no matter what it is for. This method has been checked up by the pathologist a number of times and no bacteria have been found. It is accepted that the dry autoclave is the safest method in large institutions. Boiling and heat are only resorted to in cases of sepsis.

Other methods of anæsthesia.—Several of my series have been done under complete intravenous anæsthesia, assisted by nitrous oxide and oxygen, a few have had curare, but it is my firm belief at the moment that the method of choice is the one described, namely suitable premedication, pentothal, spinal anæsthesia maintained by nitrous oxide and oxygen.

After-care.—The after-treatment is very much in the hands of the skilled nurses, who are supervised by the surgeon:—The control of the blood drip followed by water and 5% glucose for several days; the watching of the colostomy, moving of the patient, drugs, feeding and making sure that the stomach does not become dilated. To keep muscle tone and to avoid chest symptoms the patient is encouraged to get out of bed the next day or the day after. Breathing exercises are re-established as soon as possible. All these various points are watched and it is fortunate that only a very few patients have sequelæ following the operation.

Paralysis, fatalities, &c.—Except in the early days when a sixth nerve palsy was observed and temporary trouble with the bladder, no trouble has been experienced due to nerve palsies. I have had five immediate fatalities on the operating table, subsequent post-mortems have shown three with coronary thrombosis and two with a fatty myocardium. The anæsthesia was in no way to blame for any of these disasters.

Resuscitation methods have had to be resorted to on several occasions, all successfully, except in the five cases just described. Collapse was attributed either to small pulse-pressure or to the patient being kept too long in a steep-Trendelenburg position. The most important cause, however, was the patient's own chronic nervous state and collapse would have occurred no matter what operation was performed. Various attempts have been made to correct these untoward happenings.

The physician has been asked to have the chest X-rayed with special reference to the heart, a blood drip has been established, the position adjusted as far as possible and suitable medicaments given for all cases which gave us the slightest cause for anxiety. The greatest attention has been paid to the smallest detail to make sure that this operation would be successful. A great deal of this success is due to Mr. A. Lawrence Abel, who in turn was Mr. Ernest Miles' assistant and has now been responsible for the surgery of the majority of my series. His interest in the anæsthetic as well as the operation has inspired everybody to work for the patient.

Dr. Frankis Evans: Besides the abdomino-perineal excision, there are two other operations performed nowadays, the perineo-abdominal and the synchronous combined excision. In this latter operation two surgeons work simultaneously, one at the perineum and the other at the abdomen. It is claimed by the protagonists of this operation that it is possible by this method to remove growths which would otherwise be considered inoperable. Indeed, the operability figures with this operation are given as 84%.

In skilled hands the perineo-abdominal operation takes no longer than the synchronous combined method. I have seen Gabriel remove a rectum by his perineo-abdominal route in fifty to fifty-five minutes, and this is the time usually taken in the synchronous combined method.

It has been said that there is more shock associated with the synchronous operation than with the other, but I should not like to be definite on this, for I believe that the shock is largely proportional to the blood loss, and if hæmostasis is quick and accurate the loss of blood is appreciably diminished.

In the light of experience the anæsthesia for these operations has become very largely standardized. My own preference is for a spinal analgesic in combination with a dilute pentothal drip to maintain unconsciousness. This method has the advantage of blocking the upward sensory path thereby diminishing the nerve shock: it also tends to lower the blood-pressure. This is an advantage in that there is less bleeding from the perineal end, and, provided the fall of blood-pressure is not too profound, is of distinct benefit to all concerned.

The choice of spinal analgesia, whether it be a light or heavy solution, is really immaterial for it is only a question of personal preference. My own experience favours the heavy solution and I use quite a small dose in practice. I do not aim for a high spinal block and do not expect to obtain analgesia beyond the costal margin. The patient would resent exploration of the liver surface if it were not for the pentothal drip. The idea of this is to attempt to limit the blood-pressure fall as far as possible.

The technique of administration is quite simple. The patient is turned over on to the left side and the spinal tap is made in the third lumbar interspace. 1·2 c.c. of heavy nupercaine or "Spinal D" is taken up into the syringe and is expanded to 1·5 c.c. with cerebrospinal fluid. This volume is reinjected into the spinal canal. The patient is then turned over into the dorsal decubitus and placed in a 5 degrees Trendelenburg position immediately after he has been turned on to his back. The knees are flexed but the heels remain touching the stretcher. This gives the analgesia to costal margin. The intravenous drip is now set up, preferably into a vein on the right forearm. As a matter of fact I have designed, and use, a special needle cannula for this purpose. I do feel that a cannula is of the utmost importance and is very much preferred to a needle. Needles are apt to perforate veins while in situ, whereas cannulæ do not.

The intravenous drip we use at St. Mark's is that which was devised by Mr. Officer when he was R.S.O. at St. Mark's. It consists of a central mixing chamber into which two drips are fused, so that one can administer blood on the one side together with saline on the other, or if a simultaneous drip is not required it gives a quick change from one bottle of saline to the next without any cessation of drip.

If the cannula be placed in a vein in the right forearm the arm may be kept at the side of the patient, or if preferred it can be held on a board at right angles. This is not in the way of the assistant, but would interfere with the surgeon's work if it were placed in the left forearm on a board.

A blood-pressure cuff is placed upon the left arm, so that blood-pressure readings can be taken during the operation. For this purpose we use a Mendelssohn-Evans visual blood-pressure recording instrument, which works very well. As soon as the cannula is in the vein 0·4% pentothal in normal saline is run in at some 120 drops to the minute until the patient has fallen asleep. The rate of drip is then slowed to 50 or so drops to the minute, and the patient is kept in upper first plane anæsthesia, that is to say with a brisk lid reflex. As soon as the abdomen has been opened the pentothal drip rate is increased to 120 or so drops per minute again, to deepen the anæsthesia, so that the patient does not resent the examination of the liver. As soon as this has been accomplished the drip is again slowed and the patient brought back to the very light plane he was in before.

If the blood-pressure falls below 80 one can start an adrenaline drip on the other side of the Officer's apparatus. This runs concurrently with the pentothal drip. The adrenaline drip consists of 1/250,000 adrenaline and is made by adding 2 c.c. of 1/1,000 adrenaline to 500 c.c. of saline. Sometimes adrenaline oxidizes in ordinary normal saline but this can be prevented by the addition of 100 mg. of ascorbic acid from a sterile ampoule, or by bubbling carbon dioxide through the saline before adding the adrenaline. If desired the adrenaline may be added to the blood but in this case 100 mg. of ascorbic acid must be added to every 500 c.c. of blood before adding the adrenaline, otherwise the adrenaline is oxidized by the blood. If it is decided to administer adrenaline, the drip rate is adjusted to maintain the blood-pressure round about 100 to 110 mm. of mercury. There is no point in raising the blood-pressure beyond this otherwise the patient would lose blood unnecessarily. The adrenaline has certain beneficent effects: it raises the blood-pressure, thereby keeping the kidneys excreting, and dilates the coronary arteries, thereby improving the cardiac circulation. Admittedly there are theoretical risks of over-dosage which would result in ventricular fibrillation, but this only occurs with gross overdosage, and the fibrillation ceases within a minute of the drip being stopped. With reasonable care there is no likelihood of this happening and the adrenaline drip is continued post-operatively for some hours until the patient's own blood-pressure control has again come into action.

The adrenaline drip is continued post-operatively until the patient's own blood pressure control is re-established. This occurs from four to twelve hours after operation. In one of my cases the adrenaline drip was continued at intervals for two or three days post-operatively, after the patient had had considerable hæmorrhage owing to a surgical catastrophe, and it was found that her blood-pressure fell almost to nothing each time the drip was stopped. This patient made an uninterrupted recovery, and we now have quite a series of patients who undoubtedly owe their lives to this method of blood-pressure control. I do not suggest that it is necessary in every case or should be used as a routine, but where the blood-pressure falls unduly low there is the indication for adrenaline as the easiest means of keeping the blood-pressure at the level desired. Adrenaline is so rapidly oxidized in the body that the delicacy of control and the rapidity of response is one of the great advantages of the method.

As a result of this we have found that we now can tackle patients whom we would formerly have refused as being unsuitable for operation.

I have found the ordinary pressor drugs disappointing. The effects of ephedrine, methedrine and phedracin were too transient.

I have studied the figures at St. Mark's from 1939 onwards, and find that there is nothing to choose between the perineo-abdominal and the synchronous excision as regards mortality rate, which is fairly steady round 8% and 9%.

Pulmonary complications post-operatively do sometimes occur. In 60 excisions there were 8 chests, 4 of whom had bronchitis, 1 pleurisy, and 3 pneumonia. 20 patients had a spinal with gas-oxygen ether, and of these 4 had chest complications, that is 20%. Of 40 patients who had a spinal and dilute pentothal drip 4 developed chests (3 bronchitis and 1 pneumonia).

All our excision cases are given blood during the operation, and it is started after, or towards the end of, the perineal dissection. Cuthbert Dukes found by direct observation that the blood loss during these operations varies between 250 c.c. and 750 c.c. We give each patient a pint of blood, and continue with saline afterwards for thirty-six or forty-eight hours.

We have tried a few cases with curare instead of spinal, but the hæmorrhage from the perineal end was such as to hamper the surgeon, and the patients were apparently more shocked than if a spinal had been used.

In conclusion, I would like to stress the magnitude of the operation, whatever method of excision be used, and I feel that the time factor has to be considered from the point of view of hæmorrhage and resultant shock. Even so the death from carcinoma of the rectum with its ceaseless tenesmus and tormina is so distressing that we should be prepared to operate upon the so-called inoperable patients. It gives them the chance of a few months or even years of carefree life, free from pain and suffering. For these reasons I feel that we should never refuse to anæsthetize a patient upon the grounds that he is not fit to withstand the shock of the operation, or that he is too old.

Mr. O. V. Lloyd-Davies: Coupled with measures to keep the patient asleep spinal anæsthesia is, at present, the most suitable anæsthetic for combined excisions of the rectum.

In an operation of this magnitude there are, however, certain precautions to be taken and one of the most important of these is an adequate control of the blood-pressure. The turning of the patient during the operation lowers the blood-pressure very considerably and on occasion to a dangerous level.

The abdomino-perineal and perineo-abdominal methods require one or two turns respectively, but this turning factor can be completely overcome by using the lithotomy-Trendelenburg position (*Lancet*, 1939 (ii), 74). With the patient in this position the surgeon can perform either of the above methods and with two surgeons a synchronous combined excision can be performed. The intravenous adrenaline drip method of blood-pressure control has been a life-saving measure on several occasions.

The patient's response to adrenaline is usually very dramatic and care must therefore be taken to balance the rate of the drip accurately with the blood-pressure recordings. Gross fluctuations of the pressure may be serious for the patient and a rapid drip rate by which the patient is given more than half a litre of fluid in four hours may again be harmful. A falling pressure requiring an increase in the rate of drip to above this danger point should be dealt with by increasing the concentration of adrenaline solution.

If adrenaline has been used during the operation it must be continued in the ward until the normal vasomotor control mechanism recovers. This requires the constant attention of a person competent to take repeated blood-pressure recordings and to adjust the drip rate accordingly. In ideal circumstances there should be a post-operative team comparable with an operative team.

A poor-risk subject of 70 years with a massive growth made an excellent recovery after a combined excision and during the first three post-operative days he required 64 c.c. of adrenaline. At times the concentration of adrenaline was as much as 10 c.c. per half-litre.

Another interesting case of anuria thirty-six hours after a combined excision was successfully dealt with by introducing adrenaline into the drip, thereby raising her blood-pressure which was 70 mm. of mercury to her normal of 120 mm. of mercury. This case failed to respond to the usual measures.

Dr. V. Eades Vessell, having stated that the disadvantages and dangers resulting from the employment of adrenaline had been amply demonstrated by previous speakers, put in a strong plea for early blood drip transfusion during the course of the operation well before the onset of any evidence of shock. No risk was thereby incurred and, when this was done, in his opinion the post-operative work of the nursing staff was considerably lightened and the suffering and discomfort of the patient were diminished.

Dr. H. W. Loftus Dale had, for some years, used cyclopropane in conjunction with spinal analgesia for abdomino-perineal excisions of the rectum, believing that the increased oxygen used in conjunction with this agent made it preferable to nitrous oxide. Recently he had abandoned spinals in favour of curare thereby avoiding the fall in blood-pressure which accompanies movement of a patient from the Trendelenburg to the lateral position under a spinal. There was increased bleeding associated with the combination of cyclopropane and curare and he pointed out the danger of inadequate pulmonary ventilation in a patient with paresis of the diaphragm in the full Trendelenburg tilt.

Dr. Victor Goldman asked Dr. Frankis Evans if he had used methedrine instead of adrenaline as a drip infusion. Dr. Goldman was rather diffident about using adrenaline during general anæsthesia as it was his practice to maintain light anæsthesia with cyclopropane rather than nitrous oxide and oxygen. It was also his practice to add 30 mg. of methedrine to the pint of saline. Dr. Goldman also mentioned that he had anæsthetized a number of cases of perineo-abdominal resections by means of light cyclopropane anæsthesia using curare to produce muscular relaxation. There had been no complaints from the surgeons concerning the anæsthesia or increased bleeding.

The President (Dr. Stanley Rowbotham) said that his own experience of the abdomino-perineal operation extended well over twenty years, and although he had not anæsthetized as many cases as either Dr. Jarman or Dr. Frankis Evans, he had nevertheless had a fair experience of the operation, and with several surgeons. He agreed that spinal anæsthesia combined with a sleeping general anæsthetic appeared to give the best results. He was prepared to believe that curare might prove equally good, but so far he had had small experience of it in this particular field. From the small number of combined operations which he had anæsthetized he was inclined to think that patients became more shocked; perhaps because the trauma was concentrated over a shorter period of time.

He agreed with Dr. Frankis Evans that he preferred to have control of the circulation from the start, and not to wait for resuscitation until the patient had returned to bed. This meant putting up a drip before the operation started. He had used the adrenaline drip advocated by Dr. Frankis Evans many times. The idea originated from Crile; but adrenaline was only half the story; in the body adrenaline was rapidly destroyed by the ferment amylase oxidase. This ferment, however, could be fixed by ephedrine, so that if ephedrine were added to the adrenaline solution the action of the adrenaline was very considerably prolonged. He had been in the habit of using 1 c.c. of 1/1,000 solution of adrenaline and 5 grains of ephedrine hydrochloride in a half-litre bottle of saline. He had, however, given up the use of adrenaline since plasma or serum had become available, because these, having a big molecule, remained in the circulation and sustained the blood-pressure for a much longer period than did any other intravenous injection which he knew. In his opinion this was also superior to the many analeptic drugs which were available.

Dr. Frankis Evans, in reply to Dr. Goldman, said that he had not used methedrine as an infusion, but had only given it in intermittent dosage, 15 mgm. intramuscularly and 15 mgm. intravenously. He had used a combination of 1 in 250,000 adrenaline with ephedrine (gr. iii to 500 c.c.) with very satisfactory results.

Clinical Section

President—A. DICKSON WRIGHT, M.S., F.R.C.S.

[*December* 13, 1946]

Paterson-Plummer-Vinson Syndrome in a Case of Familial Acholuric Jaundice.—LEO RAU, M.D., M.R.C.P.

Miss E. S., aged 29, first seen in August 1946, complaining of dysphagia, first noticed in 1939. It occurred at irregular intervals of weeks or months, but was never severe enough to make her vomit. In 1945, she was seen by a surgeon who performed a partial thyroidectomy, but the attacks continued. They could not be connected with her periods, which were normal.

Family history.—One of her sisters has acholuric jaundice (*Proc. R. Soc. Med.*, 1946, **39**, 307), and in 1942 her mother was treated for pernicious anæmia for a period of less than three months, obviously a case of macrocytic anæmia.

20.8.46: Poor physical state, marked pallor, weight 8 st. 2 lb. No jaundice, cyanosis or œdema. B.P. 130/85. No glands palpable. No ulcers of the leg and no abnormality of the skin. There were some fissures of the lips. Spleen and liver could not be felt; there was marked atrophic glossitis; her nails were spoon-shaped, short and atrophic. With the exception of urobilinogen, no abnormality of the urine could be detected.

28.8.46: Seen after attacks of biliousness, giddiness and headaches. The serum bilirubin was 0·17 mg.% (indirect). Fragility of R.B.C. from 0·36% to 0·60% NaCl. The Price-Jones curve showed a shift to the left.

Radiological examination.—The barium swallow showed marked spasm of the œsophagus, just above the aortic knuckle, which would pass off and then allow some of the barium to reach the cardia. On reaching this area, retroperistalsis would start, until the barium had again returned to the spastic area. This interchange of spasm, peristalsis and retroperistalsis could be observed for long periods, until the œsophagus was found empty of barium. No abnormality of heart, chest, diaphragm, stomach, duodenum, or small intestine.

23.10.46: Spasm very marked, œsophagus still filled with barium after forty minutes (*see* table for blood-counts).

The President (Dr. Stanley Rowbotham) said that his own experience of the abdomino-perineal operation extended well over twenty years, and although he had not anæsthetized as many cases as either Dr. Jarman or Dr. Frankis Evans, he had nevertheless had a fair experience of the operation, and with several surgeons. He agreed that spinal anæsthesia combined with a sleeping general anæsthetic appeared to give the best results. He was prepared to believe that curare might prove equally good, but so far he had had small experience of it in this particular field. From the small number of combined operations which he had anæsthetized he was inclined to think that patients became more shocked; perhaps because the trauma was concentrated over a shorter period of time.

He agreed with Dr. Frankis Evans that he preferred to have control of the circulation from the start, and not to wait for resuscitation until the patient had returned to bed. This meant putting up a drip before the operation started. He had used the adrenaline drip advocated by Dr. Frankis Evans many times. The idea originated from Crile; but adrenaline was only half the story; in the body adrenaline was rapidly destroyed by the ferment amylase oxidase. This ferment, however, could be fixed by ephedrine, so that if ephedrine were added to the adrenaline solution the action of the adrenaline was very considerably prolonged. He had been in the habit of using 1 c.c. of 1/1,000 solution of adrenaline and 5 grains of ephedrine hydrochloride in a half-litre bottle of saline. He had, however, given up the use of adrenaline since plasma or serum had become available, because these, having a big molecule, remained in the circulation and sustained the blood-pressure for a much longer period than did any other intravenous injection which he knew. In his opinion this was also superior to the many analeptic drugs which were available.

Dr. Frankis Evans, in reply to Dr. Goldman, said that he had not used methedrine as an infusion, but had only given it in intermittent dosage, 15 mgm. intramuscularly and 15 mgm. intravenously. He had used a combination of 1 in 250,000 adrenaline with ephedrine (gr. iii to 500 c.c.) with very satisfactory results.

Treatment.—Excision head of radius and tendon transplantation. A 2-inch transverse dorsal wrist incision was made in a skin crease. Posterior annular ligament preserved, extensor tendons found to be thin and atrophic except for radial extensors. Extensor carpi radialis brevior detached from its insertion and sutured to extensor communis with fingers extended and communis tendon mass sutured together. Tendon of extensor carpi radialis longior split for about 2½ in. and one portion detached from its insertion threaded beneath posterior annular ligament with extensor pollicis longus, and sutured to that tendon with the thumb in extension.

After-treatment.—Cock-up splint for five weeks, fixing wrist and metacarpo-phalangeal joints. Interphalangeal joints moved from the first. There is now full flexion and extension of fingers and wrist and the elbow movements are normal. Scars are minimal, at dorsum of wrist and over head of radius. Patient is able to work as an artist and during the late war served throughout as an ambulance driver at home and overseas. (*See* photograph.)

Leontiasis Ossea.—J. M. WILLCOX, M.B. (for IVOR LEWIS, M.S., M.D.).

Elizabeth E., aged 55, housewife, admitted to hospital September 25, 1946.

History.—In 1929 X-ray showed what appeared to be an odontome of the left upper jaw. At operation three months later some bone was removed but the patient was told that the whole of the tumour was not removed for fear of breaking the jaw. Since 1930 her face has been slowly and steadily getting bigger. There has been no pain. The patient's only symptoms are the shape of her face and uselessness of the upper incisors.

On examination.—Bilateral enlargement of the maxillæ, making cheeks and upper jaw protrude. Subsidiary swellings both sides of nose. Alveoli enlarged and thickened. X-ray shows gross changes in both superior maxillæ with great bony thickening and a structureless sclerosis. Both antra are occluded. Middle and inferior turbinates similarly affected. Frontal bones show a few patches of sclerosis. X-ray appearances of pelvis and long bones normal. Wassermann reaction negative.

Dr. H. S. Stannus: Cases of leontiasis ossea present many points of interest; their ætiology remains unknown, their relationship to other conditions uncertain, including among them fibrocystic disease and the condition known as goundou commonly associated with yaws. Anyone interested in the subject should consult the monograph by Botreau-Roussel (1925) on "Ostéites pianiques." Some years ago I collected all the published cases of leontiasis and found I could match each one with a case from Botreau-Roussel's wonderful series. One wondered whether there was some common ætiological factor in the two conditions—possibly a nutritional factor disturbing bone metabolism. A rather similar affection occurs in caged anthropoids, equidæ and goats.

Malignant Synovioma of the Left Elbow.—RALPH SHACKMAN, F.R.C.S.

Mrs. O. S., aged 44, a housewife, was first seen in April 1940. She had rheumatoid arthritis which she said had been present for nineteen years. There were fusiform swellings of all the interphalangeal joints and all the metacarpo-phalangeal joints of the right hand. The right wrist, the right elbow and the right shoulder were all stiff. Crepitus was present in the right knee and there was ankylosis of the tarsal and metatarsal joints, a right hallux valgus and stiff inter-phalangeal joints of the right foot. The first and second digits of the left hand were swollen, the left wrist was slightly stiff: the left elbow and the left shoulder were stiff. There was crepitus of the left knee, a left hallux valgus and stiff inter-phalangeal joints of the left foot. The range of movement of the left elbow was from 35 to 160 degrees, and there was some limitation of pronation.

The koilonychia was still found on October 2, whereas the atrophic glossitis had disappeared when examined on that day.

A second fragility test (2.12.46) was again abnormal (0·32%—0·60% NaCl).

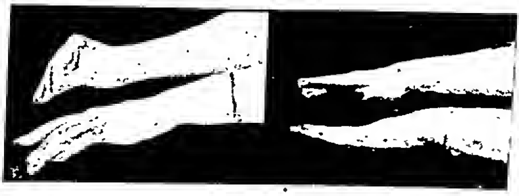
Treatment and progress.—Miss E. S. was put on Blaud's pills, b.d.ii, after the diagnosis was established on 4.9.46. There was an immediate response to this treatment.

Comment.—The leading symptom (dysphagia) in this patient is characteristic of microcytic anæmia, caused by iron deficiency. This Paterson-Plummer-Vinson syndrome, on radiological examination, could be localized to the upper third of the œsophagus, where there was marked spasm, just above the aortic knuckle. The sudden drop of hæmoglobin from 60% to 47% in the absence of any hæmorrhage suggested the probability of an acholuric jaundice, perhaps in addition to the microcytic anæmia. In favour of the presence of one of the hæmolytic anæmias —in this case acholuric jaundice—was the familial occurrence, the abnormal fragility of the R.B.C., the left shift of the Price-Jones curve, the raised reticulocyte count and the urobilinogenuria.

Dr. Herbert Levy said that this seemed to be a fortuitous combination of latent congenital hæmolytic anæmia (acholuric jaundice) and sideropenic dysphagia (Paterson-Plummer-Vinson's syndrome). In the series of cases of the latter condition reported by J. Waldenström and S. R. Kjellberg (*Acta radiol., Stockh.*, 1939, **20**, 618) and B. S. Holmgren (*Acta radiol., Stockh.*, 1943, **24**, 455) as well as in the case shown before this Section by Dr. K. P. Ball (*Proc. R. Soc. Med.*, 1945, **38**, 134) œsophageal narrowing was usually found just below the level of the cricoid cartilage whereas the present case was reported to show a transitory spasm as far down as the crossing of the aorta; strict adherence to the technique of the first-named authors might in the present case show an upper stricture besides the demonstrated abnormality. Patients suffering from sideropenic dysphagia were possibly prone to develop a retrolaryngeal or hypopharyngeal carcinoma and should be followed up for long periods with this complication in mind.

Tendon Transplantation for Posterior Interosseous Nerve Paralysis.—REGINALD A. KING, O.B.E., F.R.C.S.

Miss I. First seen on 25.5.38, aged 19. She complained of difficulty in using the right hand with inability to extend thumb and fingers at the metacarpophalangeal joints, since the age of 4, when she fell from a height of ten feet in S. Africa and fractured the right arm. The right hand was slightly smaller than the left; there was a slight prominence on the outer side of the forearm with wasting of the dorsal muscles. The head of the radius was dislocated outwards. Extensors indicis, digiti minimi, carpi ulnaris, digitorum communis and pollicis longus were paralysed. Extension of wrist was possible on the radial side as extensors carpi radialis longior, brevior and supinator longus contracted normally.



(*a*) (*b*)

Posterior interosseous nerve paralysis (*a*) before, (*b*) after tendon transplantation.

X-ray of forearm showed head of radius dislocated outwards and backwards with lengthening of radial neck.

X-rays of left elbow showed: "Joint spaces diminished with osteophytic lipping at the margins of the bones. Appearances suggest long-standing arthritis of the rheumatoid type." (This applied also to the X-ray appearances of all the clinically involved joints.)

The patient continued under supervision and made no special complaint about the left elbow until August 1946 (i.e. six and a quarter years after she was first seen) when she stated that in December 1945 she had noticed sudden pain and swelling in the left elbow. The pain and swelling persisted and were not relieved by poulticing. Now, the left elbow was swollen to the size of a grapefruit, with dilated veins in the over-lying skin. The range of movement was 90 to 135 degrees, and there was some limitation of pronation and supination. The axillary lymph nodes were not palpable. On questioning, the patient admitted to "pins-and-needles" being felt in the tips of the third, fourth and fifth fingers. The swelling was soft and felt as if it contained fluid, but aspiration failed to confirm this clinical impression. On September 27, 1946, a biopsy was carried out. A moderate amount of thickened fibrinous exudate was drained and a piece of soft tissue removed for histological examination. The wound healed by first intention.

Histological report (Dr. C. V. Harrison).—"Most of the tissue is well outside the joint in the voluntary muscle. The tissue is infiltrated by a densely cellular malignant tumour composed of irregularly rounded cells with pale-staining vacuolated nuclei and prominent nucleoli, and is devoid of any definite structural pattern. The cells appear to be of mesoblastic origin and show frequent mitoses. It is considered that this is a malignant mesoblastic tumour, probably a synovioma." Reticulum staining shows a rich network of reticulin fibrils. (*See* figs.)

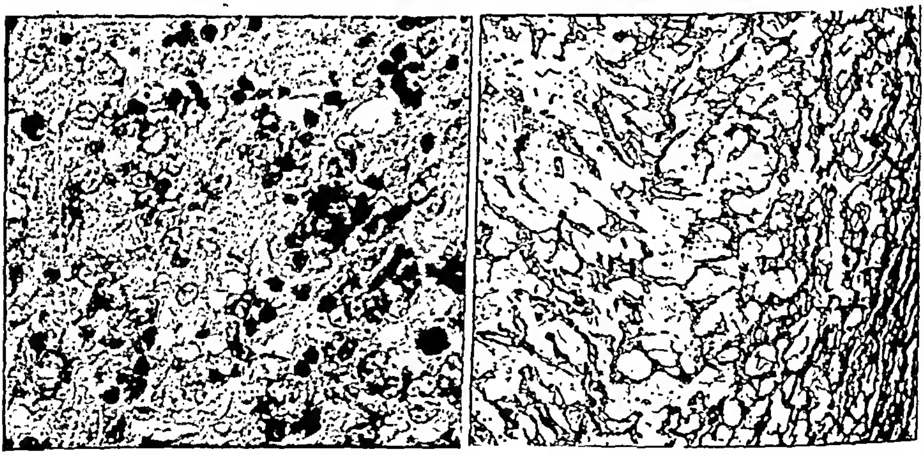


FIG. 1. ×394 FIG. 2. ×116

Malignant Synovioma of Left Elbow.

Fig. 1.—Hæmatoxylin and eosin staining. Fig. 2.—Silver impregnation, reticulum staining.

X-ray of the chest showed no metastases and a disarticulation at the left shoulder joint was performed under general anæsthesia.

Primary healing followed and convalescence was smooth. Deep X-ray therapy has been given to the shoulder. The elbow was dissected and pieces of the fleshy white tumour were taken for histology: one from the synovium of the elbow-joint, one from around the ulnar nerve, and one enlarged axillary lymph gland noted at operation. All three showed a tumour similar to that of the biopsy, but with the histology less well preserved.

Diagnosis was suggested as a result of the biopsy, which showed tissue reproducing caricatures of synovial structures with marked reticulin formation, and sarcomatous cells. The tumour appears to be of that group enunciated by Louis Berger (*Amer. J. Cancer,* 1938, **34**, 501) as the "indifferent type, of compact structure but with clear spots after reticulum impregnation, corresponding to a beginning endothelial evolution". Confirmation was obtained after disarticulation by the dissection which showed the tumour to have arisen in the soft tissues around the left elbow-joint.

Prognosis is considered to be poor in view of the series reported by Haagensen and Stout (*Ann. Surg.*, 1944, **120**, 826) who collected 104 cases of whom only 3 were known to be free from recurrence or metastasis after five years.

Transthoracic Partial Gastrectomy for Intussuscepted Fibromyoma of Fundus of Stomach.—Norman C. Tanner, F.R.C.S.

S. C., a Polish journalist aged 56, was admitted to St. James' Hospital on 30.10.46, having collapsed after three days' melæna. He stated that there had been some abdominal discomfort after meals for a few months. Six weeks previously he had vomited blood. He had been losing weight.

On examination he was found to be very pale and thin. B.P. 100/46. No mass could be felt in the abdomen. Blood-count on day of admission: R.B.C. 1,940,000 per cmm., Hb 28%. He was given a blood transfusion and early light feeding and there was no further massive hæmorrhage.

Five days after admission a gastroscopic examination disclosed the presence of a polypus of the fundus of the stomach with the "bridging folds" sign of Schindler at the base and a white polypoidal edged ulcer at its apex (*see* Plate). The mucosa of the stomach was atrophic but no other tumour of the stomach was present. Fractional test meal revealed complete achlorhydria. Later he began to get pain after meals again, and an X-ray examination about this time showed a filling defect, evidently the stalk of a mass which originated at the fundus of the stomach. The tumour itself, thinly covered with barium, appeared to be intussuscepted into the duodenum. The gastroscope was passed again at this time but unobstructed views could not be obtained, which tended to confirm that some gross anatomical distortion had taken place.

Operation.—On 29.11.46, under cyclopropane and local anæsthesia, a transthoracic transphrenic laparotomy was performed, after removing the tenth rib. The fundus of the stomach was found to be intussuscepted, the apex of the intussusception being a hard tumour lying in the grossly distended duodenum. The intussusception was easily reduced. In view of the extremely hard consistency, nodularity of the base of the tumour, enlargement of the paracardial and superior gastric lymph glands, and the persisting ulceration, a radical resection was carried out, the upper two-thirds of stomach, 3 cm. of œsophagus, spleen and neighbouring omenta and glands being removed. After closing the cut end of the lower segment of the stomach an "end-in-side" œsophago-gastrostomy was performed. The remaining stomach was securely anchored and diaphragm and chest were closed with drainage of the pleural cavity.

The post-operative progress was normal, fluids by mouth were taken on the second day, he was up on the sixth day and was discharged, taking food very well, on 21.12.46.

The specimen.—The tumour, 12 cm. by 7 cm. by 7 cm. has its base about 2 cm. from the cardiac orifice. It is hard in consistency and has an ulcer crater at the

NORMAN C. TANNER: Transthoracic Partial Gastrectomy for Intussuscepted Fibromyoma of Fundus of Stomach.

Diagnosis was suggested as a result of the biopsy, which showed tissue reproducing caricatures of synovial structures with marked reticulin formation, and sarcomatous cells. The tumour appears to be of that group enunciated by Louis Berger (*Amer. J. Cancer*, 1938, **34**, 501) as the "indifferent type, of compact structure but with clear spots after reticulum impregnation, corresponding to a beginning endothelial evolution". Confirmation was obtained after disarticulation by the dissection which showed the tumour to have arisen in the soft tissues around the left elbow-joint.

Prognosis is considered to be poor in view of the series reported by Haagensen and Stout (*Ann. Surg.*, 1944, **120**, 826) who collected 104 cases of whom only 3 were known to be free from recurrence or metastasis after five years.

Transthoracic Partial Gastrectomy for Intussuscepted Fibromyoma of Fundus of Stomach.—NORMAN C. TANNER, F.R.C.S.

S. C., a Polish journalist aged 56, was admitted to St. James' Hospital on 30.10.46, having collapsed after three days' melæna. He stated that there had been some abdominal discomfort after meals for a few months. Six weeks previously he had vomited blood. He had been losing weight.

On examination he was found to be very pale and thin. B.P. 100/46. No mass could be felt in the abdomen. Blood-count on day of admission: R.B.C. 1,940,000 per cmm., Hb 28%. He was given a blood transfusion and early light feeding and there was no further massive hæmorrhage.

Five days after admission a gastroscopic examination disclosed the presence of a polypus of the fundus of the stomach with the "bridging folds" sign of Schindler at the base and a white polypoidal edged ulcer at its apex (*see* Plate). The mucosa of the stomach was atrophic but no other tumour of the stomach was present. Fractional test meal revealed complete achlorhydria. Later he began to get pain after meals again, and an X-ray examination about this time showed a filling defect, evidently the stalk of a mass which originated at the fundus of the stomach. The tumour itself, thinly covered with barium, appeared to be intussuscepted into the duodenum. The gastroscope was passed again at this time but unobstructed views could not be obtained, which tended to confirm that some gross anatomical distortion had taken place.

Operation.—On 29.11.46, under cyclopropane and local anæsthesia, a transthoracic transphrenic laparotomy was performed, after removing the tenth rib. The fundus of the stomach was found to be intussuscepted, the apex of the intussusception being a hard tumour lying in the grossly distended duodenum. The intussusception was easily reduced. In view of the extremely hard consistency, nodularity of the base of the tumour, enlargement of the paracardial and superior gastric lymph glands, and the persisting ulceration, a radical resection was carried out, the upper two-thirds of stomach, 3 cm. of œsophagus, spleen and neighbouring omenta and glands being removed. After closing the cut end of the lower segment of the stomach an "end-in-side" œsophago-gastrostomy was performed. The remaining stomach was securely anchored and diaphragm and chest were closed with drainage of the pleural cavity.

The post-operative progress was normal, fluids by mouth were taken on the second day, he was up on the sixth day and was discharged, taking food very well, on 21.12.46.

The specimen.—The tumour, 12 cm. by 7 cm. by 7 cm. has its base about 2 cm. from the cardiac orifice. It is hard in consistency and has an ulcer crater at the apex. On inserting a probe the ulcer is found to penetrate right to the base of the tumour. Other smaller and more superficial ulcers lie on the tumour. At its base outside the stomach are several small prominences which on section were found to be a part of the main tumour. The cut surface of the tumour has an appearance similar to that of a uterine fibroid.

Histological report (Dr. Anne Gibson).—The main tumour is composed of unstriated muscle cells and fibroblasts. These cells are regular in size and staining and show no tendency to invade the atrophied layer of stomach mucosa which covers the tumour. The section of a subsidiary nodule at the base of the tumour shows similar appearances, but here many of the cells are vacuolated and the nuclei are therefore compressed. Appropriately stained sections show that this vacuolation is not due to the presence of fat. This portion of growth is surmounted by a compressed layer of fibrous tissue and there is no histological evidence of lymphoid tissue.

Comment.—Intussusception of a gastric polypus into the duodenum is a well-known complication, and it was no doubt the cause of the pain in this case. The transthoracic route undoubtedly gave the best possible approach to the tumour, and the radical resection performed would not have been possible by an abdominal route. The after-histories of leiomyomata (of which this fibromyoma must be considered a variety) show that a large number eventually become malignant. The short history of this case, the large size, persistent and multiple irregular ulceration of the tumour led to suspicion of its innocence. Histological examination shows no evidence of malignancy, although it is occasionally misleading. The deep ulceration may have persisted as a result of the prolapse into the duodenum, or it may be that it in part resulted from cystic degeneration of the tumour, a degeneration to which the gastric leiomyomata are prone.

Two Cases of Transthoracic Gastrectomy.—NORMAN C. TANNER, F.R.C.S.

I.—A. T., male, aged 42. Epigastric pain after meals for six months.

7.12.45: Admitted to St. James' Hospital with hæmatemesis. X-ray and gastroscopy revealed presence of indurated ulcer just below cardia. This failed to improve on a medical régime.

21.2.46: Operation by abdominal and left thoracic (9th intercostal space) approach. Malignant ulcer penetrating pancreas found. Radical total gastrectomy, splenectomy and two-thirds pancreatectomy performed. Union by end-to-end œsophago-jejunostomy after "Roux" mobilization of jejunum.

Histological report.—"Columnar-celled adenocarcinoma."

Progress.—Patient discharged well on 8.6.46. Is now working and has no signs of pancreatic deficiency.

II.—P. G., male, aged 45. One year increasing pallor, epigastric pain.

On examination.—Epigastric mass. 9.10.46: Gastroscopy—4 cm. below cardia ulcerated carcinoma of the stomach. 17.10.46: Operation: total gastrectomy by combined abdominal and thoracic approach with end-to-end œsophago-jejunostomy (Roux loop).

Pathological report.—Adenocarcinoma. (Specimen was shown.)

Section of Laryngology

President—NORMAN PATTERSON, F.R.C.S.

[*December* 6, 1946]

Emergency Epistaxis

By JOSEPHINE COLLIER

BLEEDING from the nose generally ceases spontaneously no matter what treatment is adopted, but when persistent it may lead to a serious degree of anæmia and occasionally it is a cause of death. In the Registrar-General's Reports epistaxis is classified under the heading of "other diseases of the circulatory system" so one cannot judge the frequency of its occurrence as an immediate cause of death but most of us must have known or heard of cases where death has followed bleeding from the nose in such a manner that whatever circulatory disease was present one must honestly say that the epistaxis was in fact responsible for death. I myself know of five such cases and conversation with medical officers in municipal and other hospitals where the elderly are catered for supports my conviction that spontaneous bleeding from the nose may be a problem worthy of serious consideration.

I do not intend to discuss either the various common local causes of epistaxis or rare conditions such as traumatic intracranial aneurysms and hereditary telangiectasis, or general predisposing factors, except in so far as the latter influence our plan of treatment. My purpose is to examine the fundamental principles which should guide us in treating emergency epistaxis, and to inquire how far our students have appreciated these principles as shown by the current methods we find employed for dealing with a condition which is frequently encountered, always disagreeable, and possibly dangerous.

Epistaxis belongs to that class of case which Wilfred Trotter classified as a relative emergency in that wise address to medical students published in his collected papers under the title "Emergency".

> "There is probably no more ancient and deeply contrived function than the natural control of hæmorrhage, and its capabilities are truly astonishing. They are, however, often underestimated, because they demand the exact fulfilment of certain conditions which are frequently with the best of intentions made impossible. These conditions are that the pressure within the bleeding vessel should be kept low and that the site of the bleeding point should be absolutely at rest. It is odd how difficult it is to get this simple principle understood, and the simple instructions that follow from it rigorously carried out. Conscientious nurse and anxious relative will conspire, the one to wash and the other to feed, in spite of categorical orders that nothing must be done or given, and exceptions to this rule will be taken for granted unless expressly forbidden.
>
> We are concerned here only with principles, and I shall but mention the one concrete example of severe epistaxis. Supposing you wish to make a serious attempt in such a case to avoid the recognized but odious alternative of plugging the nose, and to give natural arrest a real chance, this is the procedure to follow. Prop the patient well up with a comfortable inclination to one side, arrange a

large pad of wool for him to dribble into, put a dental prop between the teeth, *forbid him to breathe through the nose or swallow*, and give a substantial dose of morphia. Only by mouth breathing and a complete cessation of swallowing can the bleeding area be given the necessary and almost infallibly hæmostatic rest."

Now I do not say that every patient whose nose bleeds should be treated thus. Epistaxis from Little's area can generally be controlled by pressure with thumb or finger from outside the nostril but we would do well to impress on instructors of first-aid and school teachers that laying the patient down with wet cloths over the nose does not fulfil any of the conditions that encourage arrest of bleeding, and by allowing blood to drip into the pharynx leads to continuous swallowing, and subsequent vomiting and restlessness. The type of case for which Trotter's recommendations are most valuable is the severe epistaxis in the patient with a high blood-pressure. Here the bleeding, as likely as not, comes from deep in the nose and if it is to be controlled by packing requires specialized tools and a degree of skill that the ordinary practitioner does not always possess.

Packing is often found crowded into the anterior part of the nose possibly in front of a septal spur or deflection while blood soaks through the pack and drips into the pharynx. It is easy for specialists with head lamp, nasal speculum and forceps to see that plugging reaches the bleeding point but how many of our students get skilful at this simple manœuvre before they go into practice?

A dilatable rubber plug such as Rose's bag made from rubber finger-stall and a soft catheter will do less damage to the nasal mucosa but it does not always make pressure on the bleeding point if this is high in the ethmoidal area or in the nasopharynx.

Even skilful plugging which controls the bleeding temporarily may not prevent recurrence after the pack is removed in patients with pathological changes in the vessel walls. I have found records of several such cases.

One man, of 47, plethoric and alcoholic, was brought in from the street with severe bleeding apparently from both sides of the nose. Both sides of the nose were plugged at once by a competent registrar with adrenaline gauze. There was a history of hypertension but on admission the blood-pressure was only 100/60. The nose and post-nasal space were plugged seven times in three days but the bleeding recurred with severity a short time after each removal of the pack in spite of morphia, hæmoplastin, vitamin K, and calcium gluconate. The patient was restless, anxious, coughing and spitting and it was only when a good night's rest was obtained by brandy and paraldehyde that the bleeding stopped.

Another man of 45 who had been bleeding for four days before admission when he was found to have only 2,000,000 red cells and a hæmoglobin percentage of 46 did not stop bleeding in spite of daily packing for four days until he had blood transfusion. He was on the dangerously ill list for six days

I think we should examine the rationale of nose plugging in these cases in the light of the fundamental principles involved in the arrest of hæmorrhage. All the surgical measures used for controlling hæmorrhage, such as ligature and pressure, aim only at temporary arrest of the bleeding. Permanent arrest is a vital process the stages of which may be interrupted by sepsis as is seen in secondary hæmorrhage. That plugging the nose is productive of septic change is recognized by our insistence that no pack should be left in the nose for more than twenty-four hours. In patients with arterial disease where the muscular and elastic coats are converted into fibrous tissue, which prevents contraction and retraction of the vessel wall, thrombosis within and without the vessel must occur without hindrance as it is on clot formation alone that we can rely. Bacterial infection by means of its proteolytic ferments softens the newly-formed clot and allows the hæmorrhage to recur afresh. I believe that in patients with arterial disease it is particularly important not to disturb the natural defensive mechanism by which clotting occurs and to aim at securing hæmostatic rest by the method which Trotter advocates. Here are some notes of a case where this was satisfactorily obtained.

The patient was a woman of 35 with malignant hypertension whose blood-pressure was normally 250/150. She had a sudden massive epistaxis losing about two pints of blood. When examined by the registrar four hours later she was still bleeding freely anteriorly and posteriorly but no bleeding point could be seen. She was faint and cold with a rapid pulse and a B.P. of 190/140. She was given morphia and propped up in bed as described with a cork between her teeth. She felt dizzy for a short time, but when the registrar returned to the ward half an hour later he found the patient fairly comfortable and the bleeding stopped. He saw the patient hourly; the blood-pressure rose to 200/145 in three hours when the cork was removed. No further bleeding occurred. Another patient, a woman of 58 with a B.P. of 220/130, was found to have a pressure of 130/90 after six hours profuse epistaxis. She was treated in the same way. After an hour the bleeding had stopped completely and the B.P. was rising until three hours later it had risen to 170/100 but in spite of this no further bleeding occurred.

Not all the cases are as simple and dramatic as these and the patient who has been bleeding from the nose for several hours, who has been treated in a dilatory and ineffective manner may be so collapsed as to give rise to considerable anxiety.

I can recall an elderly patient seen many years ago, a known hypertensive, who, in spite of plugging, had been bleeding for thirty-six hours before admission. Packing temporarily controlled the hæmorrhage but it recurred each time the plug was removed. Finally the external carotid artery was ligatured under local anæsthetic. The patient died six hours later. (This operation was, I am afraid, action for its own sake which must be deplored.)

Wartime experience with blood transfusion has taught us that blood lost should be replaced. The old fear that transfusion, by raising the blood-pressure, will cause the bleeding to start again is not borne out by experience with drip methods. Indeed, it may be necessary to raise blood-pressure to save life. The collapsed hypertensive suffers the greatest risk under these conditions. The fatal case I have just mentioned had a B.P. of 110/80 on admission. There was a history of hypertension and, post mortem, generalized atherosclerosis was found. Such a patient should have a drip transfusion combined with the general measures advocated by Trotter. The restlessness and anxiety which are a prominent feature in the clinical condition of the patient who has lost much blood are quickly allayed with blood transfusion and morphia, far more effectively than with morphia alone. This was brought home to me forcibly during the war when for a time I was responsible for the ear, nose and throat work of a neighbouring Italian P.o.W. hospital in North Africa. The Italian habit of continuous coughing, hawking and spitting after any nose or throat operation quickly brought on hæmorrhage which increased the patient's agitation and restlessness, and set up a vicious circle which morphia did not control. It was only when I began giving a drip transfusion at a much earlier stage that this post-operative complication ceased to give me and the patient needless anxiety.

I do not think anyone now maintains (except to reassure his patient) that epistaxis with high blood-pressure is a safety-valve mechanism which should be allowed to pursue its course unchecked. If the physician wishes to reduce the blood-pressure by blood-letting he does it deliberately and under the control of B.P. estimations. Epistaxis is always distressing to the patient and worrying to the doctor but if the situation is handled in the way I have described, the bleeding that occurs will be beneficial to the patient and will cease before the blood loss has reached a dangerous level.

In conclusion I must refer to the value of these principles for the control of post-operative nose-bleeding. I think the most important practical point is the prevention of swallowing, i.e. the dental prop or cork between the teeth. Here is one example.

A man of 56 with a B.P. of 210/120 bled profusely from the left side of his nose on return from the operating theatre after bilateral removal of polypi and opening of the ethmoidal cells. When the registrar saw him his blood-pressure was 135/90. He was propped up, leaning on a bed-table, given morphia, reassurance and a dental prop. The bleeding soon ceased.

If the practitioner or house officer is taught to understand the principles which underlie the control of hæmorrhage, adequate treatment will be instituted at the onset of symptoms; and there will be fewer instances of intractable hæmorrhage calling for arterial ligature.

Anterior Ethmoidal Hæmorrhage

By R. G. MACBETH

AT the May Meeting of this Section in 1945 (*Proc. Roy. Soc. Med.* **38**, 620) I drew attention to the value of ligation of the anterior ethmoidal artery in certain cases of epistaxis. Since that time there have appeared reports of single cases by Reading (1945) and by Williams (1945), and an article by Weddell, Macbeth, Sharp and Calvert (1946). In this article we discussed the anatomy of the blood supply to the nasal cavities and described seven cases where severe epistaxis was controlled by this operation. (One of these cases was that reported by Williams, and culled by us from the records of a Military Hospital for Head Injuries.)

ANATOMY

As Miss Collier has said most cases of epistaxis cease spontaneously, or can be controlled readily without operation.

Severe epistaxis can be one of the most troublesome emergencies with which we in this Section are called upon to deal, and most of us can recollect anxious times when we have striven unavailingly to control such cases by repeated packing, cauterizations and transfusions. Ultimately, we may have ligated the external or common carotid artery, rather as a last resort, and in a number of cases this will have apparently succeeded in stopping the blood-flow. The majority of us, I think, have become obsessed by the idea that such epistaxis originates of necessity from an artery whose ultimate source is the external carotid system, and have forgotten that an important area of the nose is supplied ultimately from the Circle of Willis.

On an anatomical basis, therefore, we may divide epistaxis into two groups, depending upon whether it originates from the area of supply of one or the other of these main arterial systems. My colleagues and I have sought in vain in the literature for an appreciation that this point may be clinically important, and the remaining three of us owe a debt of gratitude to Dr. Weddell for pointing out why ligation of the external carotid sometimes fails in its object.

While the branches of the sphenopalatine and ethmoidal arteries anastomose freely on and in the lateral nasal walls and the septum, the former on the whole supplies the lower and more posterior parts of the cavity, and the latter supplies the upper and more anterior parts. It is also easy to understand why severe hæmorrhage occurring occasionally after antral operations is readily controlled by carotid ligature, while that occurring after an ethmoidectomy may not be controlled.

The middle concha is a convenient landmark whereby we may determine the ultimate source of bleeding, and it is usually possible during an epistaxis to get some idea as to whether the bleeding originates from above or below this structure, in front of it or behind. When such an observation has been made, and when carotid compression has been tried, and assuming that simple remedies have failed, the operative course of action should be clear. Either the external carotid or the anterior ethmoidal should be tied. We can see little point in ligating the internal maxillary artery via the transantral approach, as recommended by Hirsch (1936) and by Davis (1939), when the external carotid is so easy of access. They have suggested that failure of carotid ligation to control nasal bleeding, has been due to anastomosis of vessels across the mid-line; in our experience if carotid ligation fails the reason is that the wrong arterial system has been interrupted, and in such cases ethmoidal interruption succeeds. The difficult cases from the point of view of diagnosis are those where the bleeding appears to come from the region of anastomosis of the two arterial systems.

TYPES OF CASE

(*a*) *Injury*.—In cases of head injury there is often a fracture through the ethmoid, or through the fronto-ethmoidal suture, and this may involve the anterior ethmoidal artery or one of its main branches. These vessels lie in bony canals where they are subject to mural laceration or erosion, and where consequently they are unable to contract and retract. Thus, although they are quite small, the hæmorrhage to which they may give rise is often considerable.

In these cases bleeding may be immediate or at an interval after the original accident—i.e. it may be secondary in type, and presumably initiated by infection. Four of our cases occurred after injuries; in three of them carotid ligation had failed to stop the bleeding, and ethmoidal ligation succeeded. In the fourth this latter operation was undertaken with success as the primary and only operative measure.

I will quote two cases:

(1) F/O. S., aged 24, was involved in an air-crash in August 1944. There was hæmorrhage from the left nostril, but this subsided spontaneously. Eleven days later he had a profuse hæmorrhage; he was transfused and the nose was packed. Next day he bled again and it was noted that the bleeding originated in the olfactory cleft. Packing the nose again controlled him. Whenever the packing was removed, however, he bled profusely and had to be transfused.

The external carotid artery was exposed in the neck and tied; at that moment he coughed and expelled his packing and bled violently. The internal and common carotid arteries were then tied but this failed to diminish the bleeding. His nose was again packed and he was transfused.

Next day his nasal packing became loose and bleeding recommenced, and he was kept alive by continuous transfusion. I saw him for the first time at this stage, by which time he had received 18 pints of blood, and was losing it more rapidly than he was receiving it. After removal of the loosened pack, it was possible to confirm that the bleeding originated in the olfactory cleft; the pack was replaced and the anterior ethmoidal artery and a small accessory vessel were occluded by means of a silver clip. The pack was immediately removed, the patient bled no more, and made an uninterrupted recovery.

(2) J. B., aged 12, was struck on the nose by the leg of a chair early in July 1945. There was slight bleeding from the left nostril. Four weeks later he had his left antrum washed out by a colleague in London because of infection. Soon afterwards he went on a Thames camping holiday and on August 14, received a trivial injury to the nose from his sister. He seems to have bled a good deal into the punt, and it was only next day that he saw a doctor who packed the nostril. He came into hospital, the packing was removed, and there was no bleeding. Radiography revealed a fracture into the left frontal sinus and ethmoid.

Next day he bled again from the olfactory cleft, though not severely. The anterior ethmoidal artery was occluded under local anæsthesia, and the fracture was found to be actually involving the artery. There was no further bleeding.

(*b*) *Post-operative*.—These are really only special varieties of injury, and here sepsis is particularly likely to play a part. In such cases especially is packing not only likely to prove ineffective, but also actually dangerous because of the risk of meningitis.

I will quote one such case which, although it occurred in 1929, impressed itself vividly on my memory because of the number of nights of sleep I lost as a house surgeon in dealing with it.

A young R.A.F. officer had a submucous resection and middle turbinectomy. His post-operative period was uneventful, but on the eighth day after the operation he was taking a swing with a golf club, when he had a severe epistaxis and fainted. He returned to hospital with a nasal pack, which controlled him. Then there occurred a dreary period of treatment, when he had repeated epistaxes from the ethmoid region, always controlled by packing, but always recurring sooner or later after removal of the pack. He was transfused several times, and his external carotid and then his common carotid were tied unavailingly. He ultimately died from bronchopneumonia after the anæsthetic for the last ligation. I submit that he would have been saved if his anterior ethmoidal artery had been ligated.

(*c*) *Hyperpiesis.*—Hæmorrhage may occur from the area of the sphenopalatine artery in patients with hyperpiesis, and be readily controllable. But I believe that many of the cases in which the bleeding point is not readily found, but which is often "somewhere high up in the nose" belong to the anterior ethmoidal group, and I believe in such cases early ligature of that vessel would in many cases cut short what is often tedious treatment. One of our cases probably belonged to this group. Here this operation was the primary, only, and successful treatment after packing had failed, and the patient's Hb% had fallen to 38.

(*d*) *Idiopathic*—i.e. cases in which the cause can only be surmised or is never discovered, and where the bleeding comes from high up in the olfactory cleft. Two of our cases belonged to this group. In the one of them carotid ligation had failed; and in the other the patient was presumed to be suffering from telangiectasis of pregnancy, and when repeated packing failed, ethmoidal interruption was immediately successful.

TECHNIQUE

Anæsthesia.—Local infiltration by procaine or nupercaine is the method of choice; general anæsthesia is to be avoided because of the danger of aspiration of blood into the lungs. Infiltration and incision proceed as for external ethmoidectomy. The periosteum of the orbit is elevated from its medial wall to a depth of about 1¼ in. from the nasal bridge, when the ethmoidal vessels will be seen passing in a cuff of connective tissue to the foramen in the fronto-ethmoidal suture. Retraction of the orbital contents defines the vessels, and a silver clip is applied to them. Any accessory vessels and the posterior ethmoidal vessels can be coagulated with diathermy needle, or simply clamped and torn across (indeed diathermic coagulation may be all that is needed in the case of the main artery).

E. D. D. Davis remarked on the surprising lack of knowledge on the physiology of the blood circulation of the nose. Very little was known about the type of condition seen in the elderly patient who started to bleed in the early morning, the bleeding continuing for four or five days and then spontaneously ceasing. It was a fallacy to treat such patients lying down; they should be sitting up. He quite agreed that the bleeding point should be attacked, but he had grave doubts whether ligature of the external carotid artery was of any value at all. The difficult cases were those which arose from injury, and it was in these that one might be called upon to tie the anterior or posterior ethmoidal artery. The cases were rare—he had had only two of them in his life. He tied the posterior ethmoid as well as the anterior.

One case was that of a young soldier who bled through the night, following a blow on the bridge of the nose which ruptured the anterior ethmoidal artery, and in spite of plugging and transfusion he died of hæmorrhage. In another case there was an arteriovenous aneurysm of the internal carotid artery as a result of a fractured skull following a motor-cycle accident. The common carotid artery was ligatured but the epistaxis was repeated forty-eight hours after the temporary arrest following the ligature.

H. V. Forster recalled an occasion when he had to deal with an injured seaman in mid-Atlantic. Severe nose bleeding presented a desperate problem, which, however, was solved, after washing out the nose, by packing with ribbon gauze soaked in compound tincture of benzoin, a method recommended by the late Dr. Ballinger of Chicago. Adrenaline impregnated gauze had become very foul in situ but the benzoin preparation did not and was retained with success for two to three days.

A late senior medical colleague of his suffered from intermittent nose bleeding, but a period of two years' observation passed before he was actually seen in an attack. The source being the ethmoid area to which a small pack was applied with permanent success.

In severe cases needing a choanal pack by the post-nasal route, a piece of tethered sorbo rubber sponge served very well, but in very nervous subjects small tethered pieces of this material could be passed one by one through the desensitized nasal passage into the nasopharynx and then gently drawn forwards as a group to fill the choana.

E. J. Gilroy Glass: I would like to draw attention to the necessity for routine cleansing of the nose, and removal of blood clot after nasal packs have been removed. Until this has been done the patient must be instructed not to inspire through the nose lest he dislodge a clot.

This danger was illustrated by a case in Nottingham just before the war. The patient was brought to hospital with his nose already packed. When the pack was removed bleeding had ceased, but there was still some clot in the nose. While the house surgeon was preparing to remove the clot, the man inspired forcibly through the nose and dislodged a large post-nasal clot, which entered the trachea and blocked both bronchi. Death supervened in a few seconds—long before any steps could be taken to remove the clot.

This cause of death may be an unusual one following epistaxis but it is preventable if the danger is realized.

L. Graham Brown said that packing the nose, after desensitizing, was the most important factor. Provided one did that first of all after irrigating the nose, by packing in a strip of cotton-wool soaked in 10% cocaine, it was comparatively easy, and usually successful. This was so much so that in most instances one could readily see any bleeding from the anterior septal area, or, if this was not the case, one could conclude that it was either higher up in the nose, or posteriorly. In the latter case one needed only to pack back on to the anterior surface of the sphenoid. He advocated the use of the narrowest ribbon gauze, namely, ¼ in. Widths of 1 in. or ¾ in. gauze could not be packed successfully. With the ¼ in. one got control, and this control could be confirmed by looking into the mouth to see if any bleeding continued to run down below the level of the soft palate.

Even in cases of new growth and in post-operative conditions, his experience had been that these vessels had to be tied very rarely indeed. He agreed with Miss Collier when she said that most cases could be controlled by direct pressure. In an external ethmoidectomy, for example, one did not bother very much about tying the anterior or posterior ethmoidal artery. Only in cases of trauma where the bone might be fractured and where the bleeding went on for some other reason did he see the need for tying these vessels. Again, in cases of new growth he had found that diathermy controlled the hæmorrhage sufficiently. In post-nasal pharyngeal tumours he had made use of a marine sponge packed into the nasopharynx and kept firmly in place by tapes passing out through the anterior nares, and with this in place for twenty-four hours, copious hæmorrhage, from the nasopharynx, after removal of a nasopharyngeal tumour, had been controlled. It was necessary to teach students, house surgeons, and general practitioners, if possible, that desensitization of the nose as a preliminary to packing made the latter a comparatively simple procedure.

Michael Vlasto said that when a condition of hyperpiesis was present, he had always considered it wise to refrain from any precipitate attempt to stem the epistaxis. He recalled a circumstance many years ago, when a senior anæsthetist with a high B.P. developed a severe epistaxis. In what he later regarded as an excess of enthusiasm, the epistaxis was effectively stemmed. A few days later the patient died of intracranial hæmorrhage.

Eric Watson-Williams said that he had had two cases of hyperpiesia in which treatment for nasal bleeding was disastrous. He thought there must be solid ground for the view that nose-bleeding was a safety valve in hyperpiesia.

T. B. Jobson said that he had a patient, a lady of 70, who had nose-bleeding about every month. An application of radium was made, and she remained free for six months, but after that the bleeding started again. He would welcome opinions on the advisability of further radium treatment.

CASES

Choanal Atresia.—T. M. Boyle.

T. M. Boyle said that he presented this patient for advice. She had suffered from nasal obstruction all her life. She had had two previous operations.

L. Graham Brown said that he had had experience of these cases, not only unilateral but bilateral. His procedure was to do a septal operation first and remove the posterior border of the septum. This allowed sufficient facility for the opening one was going to make. He made the opening with a suitable instrument, very often using the old-fashioned frontal sinus rasp. The bony opening was enlarged in that way on the outer side of the posterior choana. The other method was to put in a circular tube through the nose and out through the mouth, and keep rotating it for a period of ten days or more. The important point in the former method was to take away the bony posterior portion of the septum.

The President said that he entirely agreed with Mr. Brown as to the importance of removing the posterior part of the septum. He had operated on only two cases, one of which was a success.

E. D. D. Davis said that he would remove a little of the hard palate as well, because in these cases of atresia the floor of the nose came up almost to the body of the sphenoid.

Pemphigus of Pharynx.—H. S. Sharp.

Mrs. B., aged 65. She was seen at hospital on 11.10.46, complaining of sore throat for one month, following extraction of teeth. Blebs and blisters started on both shoulders at the same time. No previous attacks and no significant past illnesses. Examination showed pemphigus affecting soft palate, pharynx, left side of tongue and left buccal mucous membrane. The left arytenoid was also affected and left pyriform fossa contained mucopurulent fluid. The blebs on her arms were those of pemphigus. W.R. negative. Throat swab: no pathogenic organisms. Blood-count: R.B.C. 5,750,000; Hb 94%; C.I. 0·82; W.B.C. 7,800 (polys. 72%, eosinos. 1%, basos. 0, large monos. 3%, lymphos. 24%).

E. D. D. Davis said that he had gained the impression that the incidence of pemphigus had increased. All the cases presented the same sort of feature, that is to say, little blisters first of all on the soft palate, and then on the mucosa of the check, and again on the edge of the epiglottis. These blisters would break down, and little yellow sloughs would appear and disappear leaving a raw area which became painful. He had a doctor under his care with severe pemphigus of the mouth and chest. He had salvarsan, penicillin, various drugs from America of different descriptions. Of local applications, sulphathiazole powder did not help him. What *did* relieve him was aspirin-phenacetin mixture and painting the painful surface with pure carbolic.

Gummatous Destruction of Nasal Septum: Perforating Epithelioma of Nose.—H. S. Sharp.

Mr. J. D., aged 52, married, with one child. He was a brewer's employee. There was no history of primary specific infection or significant past illnesses. He had a cleft palate in youth. He was first seen at Charing Cross Hospital on 16.8.46 complaining of rapidly growing "spot" on nose. He had had nasal discharge and crusting off and on for years. The appearance was that of complete destruction of nasal septum and a perforating ulcer of nasal soft tissues. W.R. was positive (titre 60+). Biopsy of ulcer margin showed epithelioma grade I, with heavy infection.

An Aid to Swallowing after Laryngo-Pharyngectomy for Post-Cricoid Carcinoma (*Patient and prosthesis shown*).—H. A. Kidd.

Mrs. E. H. S., aged 54. Admitted to St. Helier's Hospital on 18.6.46 with a history of dysphagia and aphonia. She had been in bed for one week before admission to hospital. Considerable loss of weight. Stridor present.

Past history.—Left mastectomy eight years ago for, probably, benign condition.

On examination.—Thin, wasted patient. No glands palpable in neck. X-ray of chest negative. Laryngoscopy showed ulceration of the posterior part of the arytenoids and fixation of the cords in adduction. The blood-pressure was 162/105.

Operation (22.6.46).—Anæsthesia—local infiltration of decicain and adrenaline. Total laryngo-pharyngectomy was performed, and only two enlarged glands were found on the right side when block dissection of glands was carried out. Blood transfusion 2 pints. The specimen showed squamous celled carcinoma which extended downwards in the mucosa of the œsophagus for 2 in. Microscopic section of the glands did not show any malignant deposits.

Post-operative treatment.—Penicillin injections and sulphathiazole. Feeds through œsophageal tube.

Convalescence uninterrupted. Discharged from hospital on 7.7.46.

A Gluck's tube was found to be unsatisfactory, and the prosthesis now being worn was made by Mr. Arthur Bell, L.D.S., and has enabled the patient to swallow her saliva without leak, and to take liquids and semi-solids. The prosthesis was modelled in plaster of Paris and then made of acrylic resin. It is attached to a 4 in. rubber tube and passes down the œsophagus and acts as a fitted funnel to the œsophagus. It collects the food as it passes over the skin between the pharyngeal stoma and the lower cut end of the œsophagus. Unlike the Gluck's tube it does not attempt to fit into the irregular and constantly altering shapes of the pharyngeal stoma.

Lionel Colledge said that the apparatus seemed to work very well in Mr. Kidd's patient. He had never found any eventual difficulty with Gluck's tube if one had several sizes made and cut them carefully, but recently the rubber was of poor quality. He did not have many cases of this sort nowadays: they were treated by radium. Some figures were published in the Lettsomian Lectures of the Medical Society of London three years ago. He thought that with regard to this particular patient the only thing left for her was to have some radiotherapy. Some cases which had had recurrences over several years had been improved and sometimes apparently permanently healed after radiotherapy.

E. Musgrave Woodman congratulated the exhibitor on the apparatus he had supplied for his patient which seemed to work extremely well. Was it not possible to deal surgically with the small recurrent area? If the further portion of that substance could be taken away surgically, even if a certain amount of deformity resulted, it was better than depending on radiotherapy. In that area radiotherapy produced a transient improvement rather than a radical cure.

Recurrent Chondroma of the Subglottic Region.—F. C. W. Capps.

E. W. A., male, aged 74.

On examination.—First seen in April 1937 complaining of six months' hoarseness. Slight inspiratory stridor. On laryngoscopy, had smooth swelling in the subglottic region which appeared to surround the whole lumen, but was most marked on the posterior aspect. Direct laryngoscopy, and high tracheoscopy showed a hard smooth swelling about ½ in. from back to front and 1 to 1½ in. deep on the posterior wall of the trachea. A piece was removed for examination. There was no bleeding.

Pathological report.—Tumour is a chondroma which is ossifying in parts, and also shows areas of calcification. Some of the fragments show much fibrino-purulent material on the surface. The tumour does not appear to be malignant.

Operation (26.4.37).—Anæsthetic—Gas and oxygen through tracheotomy tube. Laryngofissure and opening of the upper part of the trachea. The tumour, lying in the posterior wall of the larynx below the vocal cords was defined. It was found to have an irregular surface; to be moderately soft with cartilaginous areas in parts. This mass was removed by curetting with a sharp "Volkmann's spoon", leaving the post-laryngeal wall fairly clean. Throughout the operation care was taken to prevent any blood from going down the trachea. The wound was packed with flavine gauze which was brought out above a large tracheotomy tube. The larynx closed by Michel clips. Recovery was uneventful.

When seen again in June 1946 was found to have hard nodular swellings on both sides of the scar in the neck. The left cord was fixed; the right showed limited abduction. He has an adequate airway if he is careful.

H. V. Forster said that many years ago a doctor friend came to see him for loss of voice. There was immobility of one cord. The patient came to London later and was operated on by the late Sir James Berry. Its cause proved to be a chondroma. The growth had not been approached by laryngofissure which he thought was a route favoured by laryngologists.

Persistent Epiphora following Acute Dacryocystitis.—Brian Reeves.

This case had had a dacryocystorhinostomy and was shown to demonstrate an alternative approach to the lacrimal sac and duct. The patient's epiphora had subsided completely and the scar of the operation was almost invisible. The lacrimal duct was exposed as in Norman Patterson's external sinus operation. The somewhat extensive exposure was justified by the ease and accuracy with which the anastomosis could be made into the atrium of the nose. After the operation was completed a loop of nylon was threaded through the punctum into the nose, the two ends were tied and left in situ for seven days.

Slides were shown to demonstrate the steps of the operation.

L. Graham Brown said that a number of these cases could be done intranasally, especially with a wide nose. If one could see the sac made obvious by a stylet passed down the sac from above, one could take out a snippet with a suitable instrument and by irrigation of the lacrimal sac maintain patency into the nose. He congratulated the President and Mr. Reeves on an excellent result, but he thought it was an elaborate technical operation which in many cases was not necessary.

The President said that he had tried in several cases what Mr. Graham Brown had just suggested, but the results were not satisfactory. Ophthalmic surgeons, he thought, were now favouring an external route of approach.

Brian Reeves also said that he had tried the intranasal operation but found it too difficult.

H. V. Forster said that Thomas Guthrie had described a method of delivering large pieces of nasopharyngeal fibroma through the nose by doing a resection of the pyriform aperture and some years ago a Scandinavian rhinologist had suggested approaching the lacrimal sac by this route and proceeding by submucous resection of the intervening parts.

He was grateful for the suggestion to pass a nylon strip to keep the lacrimal channel patent.

days or more. The important point in the former method was to take away the bony posterior portion of the septum.

The President said that he entirely agreed with Mr. Brown as to the importance of removing the posterior part of the septum. He had operated on only two cases, one of which was a success.

E. D. D. Davis said that he would remove a little of the hard palate as well, because in these cases of atresia the floor of the nose came up almost to the body of the sphenoid.

Pemphigus of Pharynx.—H. S. Sharp.

Mrs. B., aged 65. She was seen at hospital on 11.10.46, complaining of sore throat for one month, following extraction of teeth. Blebs and blisters started on both shoulders at the same time. No previous attacks and no significant past illnesses. Examination showed pemphigus affecting soft palate, pharynx, left side of tongue and left buccal mucous membrane. The left arytenoid was also affected and left pyriform fossa contained mucopurulent fluid. The blebs on her arms were those of pemphigus. W.R. negative. Throat swab: no pathogenic organisms. Blood-count: R.B.C. 5,750,000; Hb 94%; C.I. 0·82; W.B.C. 7,800 (polys. 72%, eosinos. 1%, basos. 0, large monos. 3%, lymphos. 24%).

E. D. D. Davis said that he had gained the impression that the incidence of pemphigus had increased. All the cases presented the same sort of feature, that is to say, little blisters first of all on the soft palate, and then on the mucosa of the cheek, and again on the edge of the epiglottis. These blisters would break down, and little yellow sloughs would appear and disappear leaving a raw area which became painful. He had a doctor under his care with severe pemphigus of the mouth and chest. He had salvarsan, penicillin, various drugs from America of different descriptions. Of local applications, sulphathiazole powder did not help him. What *did* relieve him was aspirin-phenacetin mixture and painting the painful surface with pure carbolic.

Gummatous Destruction of Nasal Septum: Perforating Epithelioma of Nose.—H. S. Sharp.

Mr. J. D., aged 52, married, with one child. He was a brewer's employee. There was no history of primary specific infection or significant past illnesses. He had a cleft palate in youth. He was first seen at Charing Cross Hospital on 16.8.46 complaining of rapidly growing "spot" on nose. He had had nasal discharge and crusting off and on for years. The appearance was that of complete destruction of nasal septum and a perforating ulcer of nasal soft tissues. W.R. was positive (titre 60+). Biopsy of ulcer margin showed epithelioma grade 1, with heavy infection.

An Aid to Swallowing after Laryngo-Pharyngectomy for Post-Cricoid Carcinoma (*Patient and prosthesis shown*).—H. A. Kidd.

Mrs. E. H. S., aged 54. Admitted to St. Helier's Hospital on 18.6.46 with a history of dysphagia and aphonia. She had been in bed for one week before admission to hospital. Considerable loss of weight. Stridor present.

Past history.—Left mastectomy eight years ago for, probably, benign condition.

On examination.—Thin, wasted patient. No glands palpable in neck. X-ray of chest negative. Laryngoscopy showed ulceration of the posterior part of the arytenoids and fixation of the cords in adduction. The blood-pressure was 162/105.

Operation (22.6.46).—Anæsthesia—local infiltration of decicain and adrenaline. Total laryngopharyngectomy was performed, and only two enlarged glands were found on the right side when block dissection of glands was carried out. Blood transfusion 2 pints. The specimen showed squamous celled carcinoma which extended downwards in the mucosa of the œsophagus for 2 in. Microscopic section of the glands did not show any malignant deposits.

Post-operative treatment.—Penicillin injections and sulphathiazole. Feeds through œsophageal tube.

Convalescence uninterrupted. Discharged from hospital on 7.7.46.

A Gluck's tube was found to be unsatisfactory, and the prosthesis now being worn was made by Mr. Arthur Bell, L.D.S., and has enabled the patient to swallow her saliva without leak, and to take liquids and semi-solids. The prosthesis was modelled in plaster of Paris and then made of acrylic resin. It is attached to a 4 in. rubber tube and passes down the œsophagus and acts as a fitted funnel to the œsophagus. It collects the food as it passes over the skin between the pharyngeal stoma and the lower cut end of the œsophagus. Unlike the Gluck's tube it does not attempt to fit into the irregular and constantly altering shapes of the pharyngeal stoma.

Lionel Colledge said that the apparatus seemed to work very well in Mr. Kidd's patient. He had never found any eventual difficulty with Gluck's tube if one had several sizes made and cut them carefully, but recently the rubber was of poor quality. He did not have many cases of this sort

REHABILITATION IN CHEST INJURY

Mr. T. Holmes Sellors: Before it can be assumed that the surgeon's task is complete, the patient must be restored to mental and physical fitness. Certain branches of surgery have developed more adequately than others the control of the patient between the active phases of illness and his return to work, and among these chest surgery can claim to play an active part.

Some of the reasons for this lie in the fact that time taken for convalescence and re-education within the chest hospital or unit is on the whole very much longer than that obtaining in most aspects of general surgery. This time factor resembles more that of the sanatorium than the busy urban hospital, and even though there is no excuse for waste of time in a chest unit, experience has shown us that attempts to treat cases too often as out-patients have not met with adequate success. For example, in cases of chronic empyema, in which control of the dead space, cavity and tube is of the utmost importance, it has been found more economical in the long run to maintain these patients in hospital under observation until cure has been effected. This relatively long-term policy does not, however, become necessary in all branches of chest surgery, but exists in its most exaggerated form in surgical cases of tuberculosis and chronic chest suppurations. Many straightforward cases can be restored as virtually fit for their former occupations in the space of two or three months, but the difficult cases, as has been said, are those whose control may cover a period of one or even two years. It is to this latter group that most of the later comments will refer.

For convenience, any discussion on rehabilitation can be divided into two main sections—general and local—that is, the handling of the patient as a whole and the more local restoration of chest functions.

General.—The patient, on admission to chest hospital or unit, may develop after some weeks or months a physical and moral lethargy which must be combated at every turn if the general condition allows. The necessity for maintaining chest cases in bed for a long period is not usual, and most patients can be up and about for a considerable period of the day once the acute stages of illness are over. They should not be allowed to slouch around the wards in dressing gown and slippers, but should dress, wear shoes, and in general comport themselves as ordinary individuals. There is a great deal to be said for setting a certain routine—small tasks or jobs which help to fix the day's timetable; and a certain amount of physical exercise, walking in the hospital grounds, or even games may be permitted, so as to encourage muscular redevelopment and general body tone. There is no necessity to keep the patient within the hospital gates if the surrounding amenities permit of greater activities.

With the added freedom that obtains in a hospital in the country, there is a good case to be made out for the unit's location away from built-up areas, since the value of an open environment must inevitably play a considerable part in recovery.

Diet must be carefully planned. Some patients lose a lot of protein in their discharges, and this loss must be adequately replaced. The menu should be varied as the patient may be in the unit for months and the importance of variety and imagination in his diet must be considered.

The most difficult part of the general treatment, however, is the psychological aspect. The patient who is at first interested and energetic may easily become apathetic in a period of time, and deteriorate into that unfortunate state known as "hospitalization". This requires the utmost energy on the part of the staff to combat, and one looks forward to the day when the greater use of occupational

The President said that another method of approaching the duct was through the antrum. He had seen this route employed by a German surgeon. By the method here exhibited it was possible owing to the good exposure to see what one was doing.

Recurrent Papillomata and Webbing of the Larynx.—D. F. A. Neilson.

Man aged 49, who was gassed in 1918 and states that his voice has never been quite normal since then. In 1931-1940-1942 he underwent endolaryngeal operations for removal of papillomata and subsequent to the last operation he was given a course of deep X-ray therapy. Six applications over a period of six weeks. Total dosage 2000 r. Microscopic examination on several occasions revealed no evidence of malignancy. Two patches of papillomatous growth were removed from the upper surface of the web adhesion uniting the anterior thirds of the right and left cords. A large pedunculated papillomatous mass was removed from just below the left vocal cord, the size of a large pea. There was improvement for a time, but the patient has now relapsed and the papilloma below the cord has recurred along the under-surface.

The case was shown for suggestions as to re-treatment, and to demonstrate the danger of injury to the glottis being followed by adhesion of the edges of the vocal cords.

Congenital Bilateral Fistula of Tear Duct. One Side Treated by Toti's Operation.—J. F. Simpson.

The patient was a boy of 7. The lacrimal duct opened on the face about ¼ in. below the inner canthus. A thick mucopurulent discharge had exuded from these fistulæ since birth, and epiphora had been present. An X-ray examination with lipiodol injected into the fistulæ, showed a dilated duct and sac without drainage into the nose. The patent inferior canaliculi were well demonstrated. A right dacryocystorhinostomy was performed on November 22, with excision of the fistula. Epiphora had ceased on this side, and it was proposed to operate on the left side shortly. No bougies had been passed. The case was shown because of the comparative rarity with which such a congenital deformity was seen.

Osteoma of Nasopharynx.—A. W. McCay.

G. S., male, aged 46. Gradually increasing nasal obstruction on the right side for the past two and a half years. Right nostril now completely obstructed, the left partially. Hard bony tumour filling the right choana and partially obstructing the left. This bony mass can be palpated through the right nostril of which it appears to fill the posterior third. X-ray photographs show the bony mass but do not give any indication as to its site of origin.

EXHIBIT

Preliminary Model for an Indirect Laryngoscope.—W. O. Lodge.

The buccal portion is tubular. The pharyngeal spatula is mechanically depressed through a right angle by closure of the handle, taken from a Ballenger's guillotine. A siphon tube to warm the mirror is fitted. The lighting unit is detachable. The instrument can be sterilized by boiling. After other improvements in the design have been made, portions of the metal will be cut away to allow of the passage of instruments.

President—FRANK COOKSEY, O.B.E., M.D.

[*January* 8, 1947]

REHABILITATION IN CHEST INJURY

Mr. T. Holmes Sellors: Before it can be assumed that the surgeon's task is complete, the patient must be restored to mental and physical fitness. Certain branches of surgery have developed more adequately than others the control of the patient between the active phases of illness and his return to work, and among these chest surgery can claim to play an active part.

Some of the reasons for this lie in the fact that time taken for convalescence and re-education within the chest hospital or unit is on the whole very much longer than that obtaining in most aspects of general surgery. This time factor resembles more that of the sanatorium than the busy urban hospital, and even though there is no excuse for waste of time in a chest unit, experience has shown us that attempts to treat cases too often as out-patients have not met with adequate success. For example, in cases of chronic empyema, in which control of the dead space, cavity and tube is of the utmost importance, it has been found more economical in the long run to maintain these patients in hospital under observation until cure has been effected. This relatively long-term policy does not, however, become necessary in all branches of chest surgery, but exists in its most exaggerated form in surgical cases of tuberculosis and chronic chest suppurations. Many straightforward cases can be restored as virtually fit for their former occupations in the space of two or three months, but the difficult cases, as has been said, are those whose control may cover a period of one or even two years. It is to this latter group that most of the later comments will refer.

For convenience, any discussion on rehabilitation can be divided into two main sections—general and local—that is, the handling of the patient as a whole and the more local restoration of chest functions.

General.—The patient, on admission to chest hospital or unit, may develop after some weeks or months a physical and moral lethargy which must be combated at every turn if the general condition allows. The necessity for maintaining chest cases in bed for a long period is not usual, and most patients can be up and about for a considerable period of the day once the acute stages of illness are over. They should not be allowed to slouch around the wards in dressing gown and slippers, but should dress, wear shoes, and in general comport themselves as ordinary individuals. There is a great deal to be said for setting a certain routine—small tasks or jobs which help to fix the day's timetable; and a certain amount of physical exercise, walking in the hospital grounds, or even games may be permitted, so as to encourage muscular redevelopment and general body tone. There is no necessity to keep the patient within the hospital gates if the surrounding amenities permit of greater activities.

With the added freedom that obtains in a hospital in the country, there is a good case to be made out for the unit's location away from built-up areas, since the value of an open environment must inevitably play a considerable part in recovery.

Diet must be carefully planned. Some patients lose a lot of protein in their discharges, and this loss must be adequately replaced. The menu should be varied as the patient may be in the unit for months and the importance of variety and imagination in his diet must be considered.

The most difficult part of the general treatment, however, is the psychological aspect. The patient who is at first interested and energetic may easily become apathetic in a period of time, and deteriorate into that unfortunate state known as "hospitalization". This requires the utmost energy on the part of the staff to combat, and one looks forward to the day when the greater use of occupational therapy will be able to interest patients to a far wider extent than is possible at the present, when materials and staff are limited. Occupational therapy should not aim at being a commercial proposition. It should be an adequate relaxation with a certain amount of mental and manual exercise for the patient, though it is admitted that on some occasions the patient may find himself in later times more suited to a job which had its base in the occupational therapy he learned in the hospital. The prime object is, however, to aim at returning patients to their original vocation, and to encourage their activities in such a way that the change over from hospital to normal economic life is not too sharp.

The degree of psychological and emotional stress produced by the economic position is a further point that is not dealt with sufficiently fully. The invaluable work of hospital almoners and others helps to mitigate hardship, but often, though the pecuniary loss to the family may not be the main factor, the man's worries require most sympathetic and comprehensive handling.

Local.—The much more technical aspect of rehabilitation for the thoracic worker is concerned with actual chest functions. The effect of most thoracic diseases is to diminish chest movements, and to leave the thorax and therefore the lung in a contracted position. The chest becomes flattened and scoliosis may develop rapidly (fig. 1). The ribs become approximated and rigid, leading to diminished movement and function.

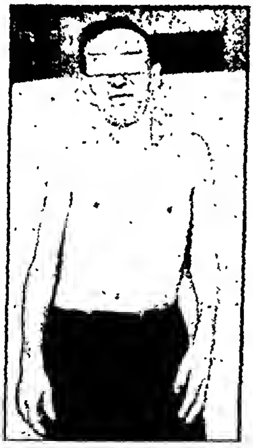

FIG. 1.

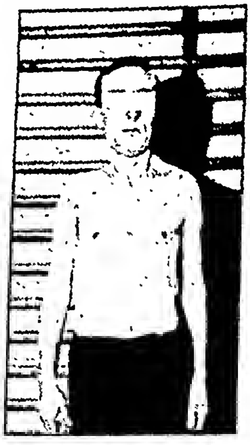

FIG. 2.

FIG. 1.—Posture and deformity following infected hæmothorax (left). The upper ribs and part of the brachial plexus were damaged. The chest was drained.

FIG. 2.—After three months' treatment considerable improvement has been obtained. The empyema is not yet closed.

The comments under this heading for convenience will be confined to chronic empyema, whose treatment illustrates most of the features that will be discussed.

Some degree of chest contraction and deposition of fibrin on the pleural surfaces can occur quite rapidly, but the remedy and restoration of movement may take a long time. It is therefore absolutely essential to institute treatment as early and energetically as possible. It may be assumed that where the chest wall moves freely and actively the underlying lung will be functioning efficiently, and similarly should lung function be lost subsequent contraction of the chest is almost inevitable.

The active movements of the chest must be instituted by the efforts of the patient himself, and started at the earliest possible moment, to be continued through the whole period of treatment and well into normal life. Only in this way can we hope to regain that full function which disease may have abolished.

From the medical and nursing point of view there are certain important details to be observed. Circular bandages or constricting dressings must be avoided, and in bed the posture of the patient requires to be watched continually. In bed in the semi-sitting position the patient tends to develop a marked kyphosis, and frequently slumps towards the affected side, exaggerating his deformity and producing scoliosis.

The exercises to re-establish chest movement are essentially based on *inspiratory* efforts. The old idea of using blowing efforts to aid re-expansion of lung are almost valueless and should not be employed. The active inspiratory exercises that have been devised depend on the establishment of energetic and localized movement of the part of the chest wall indicated. The physiotherapist, having analysed the deformity or, in the case of an empyema, the area of the dead space, starts by making pressure with the hand over the chest wall, and encouraging the patient to expand and even actively push that hand away. After voluntary control has been established by the patient, these exercises can be undertaken without constant supervision but they should be continued not for minutes but for several hours each day. Lack of concentration and failure to persist cannot achieve a good result. The physiotherapist, treating an individual or a class, is there to see that the exercises are properly done, and to control the way and degree of expansion that is being obtained. It is up to the patient to put this into practice. These localized pressure cxpansion exercises are the work of a few pioneers, and the subject is far too little known from the practical aspect. My association with Miss Reed, Miss Thacker and others at Harefield has enabled me to judge what efficient results can be obtained by carefully devised and above all conscientiously controlled exercises.

In general the chest movements can be divided into two groups. The movement of the lower ribs both laterally and anteriorly are important, and also a certain amount of posterior expansion can be obtained. Furthermore there are the diaphragmatic movements which aid basal re-expansion to a great extent (fig. 6). At the apex the only effort that can be made for practical purposes is the anterior expansion (fig. 3).

There are several points that have to be observed in these breathing exercises apart from those already mentioned. These include maintaining the chest steady except for the area that is being exercised, and seeing that sufficiently firm pressure is made over that area while the inspiratory effort is being made. Broad webbing belts are also useful in concentrating the effort, and if these exercises are done in front of a mirror or in class some of the more common errors can be counteracted.

In some other conditions of chest surgery, such as thoracoplastic operations, breathing exercises on a less severe scale will be used to encourage the patient to make use of parts of the lung away from the operation area, and to increase the respiratory function. The question of posture of the patient is most important, and is incidentally one of the helpful reasons for having the patient out of bed. The traditional nursing arrangement of pillows in the form of a "V" is not always desirable, since it encourages kyphosis and prevents the patient holding himself in a good posture. Several pillows arranged across the patient's back are preferable to a "V"-shaped arrangement, and at all times we give the patient "the freedom of the bed" at the earliest possible moment (fig. 8).

The importance of coughing in chest diseases to eject sputum is more part of actual operative after-treatment than of rehabilitation, but if there is any sputum persisting after operation, then regular and purposeful coughing or even postural drainage must be instituted.

Thoracotomy incisions frequently divide some of the scapular muscles, and re-establishment of arm movement from the very early post-operative days is important (fig. 9). During the latter stages a continual check should be made to see that the arm is being freely and actively used if healing has been normal.

The regular measurement of the vital capacity is of considerable help both to

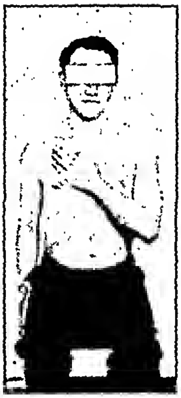

FIG. 3.

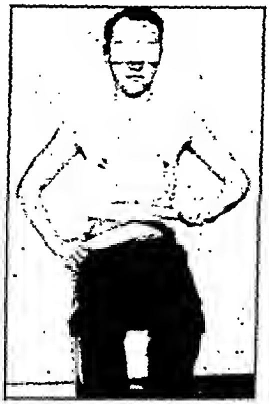

FIG. 4.

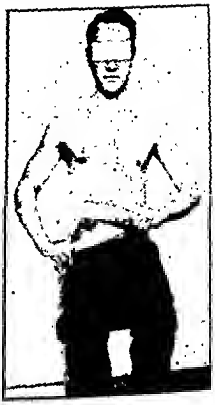

FIG. 5.

FIG. 3.—Apical expansion. Fingers are pressed against the upper ribs below the right clavicle. This helps to concentrate the inspiratory effort and movement.

FIGS. 4 and 5.—Lateral basal expansion (right). Use of belt which makes pressure against the ribs. Right hand is held still, while movement of the left hand demonstrates the degree of excursion obtained. Note absence of spine flexion. (4) Inspiration. (5) Expiration.

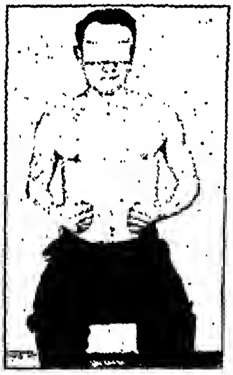

FIG. 6.—Localized expansion breathing exercises. Right empyema (Mr. Vernon Thompson's case). Diaphragmatic breathing: pressure is exerted in the costal margins by the knuckles as the abdominal wall is contracted and relaxed (inspiration).

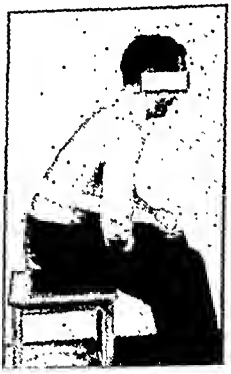

FIG. 7.—Posterior basal expansion. Use of belt with right hand stationary, and the left hand showing degree of movement obtained (inspiration).

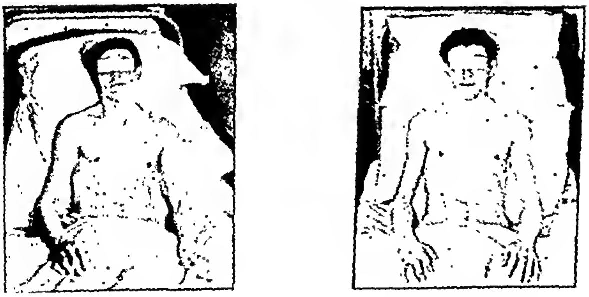

FIG. 8 (*a*). FIG. 8 (*b*).

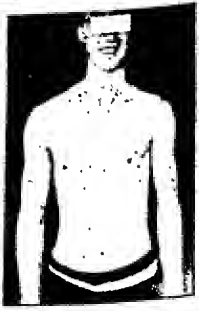

FIG. 9.

FIG. 8.—Posture in bed following thoracic operation. (*a*) Incorrect: showing kyphosis and lateral flexion of trunk. Note typical appearance of head and neck; pillows are badly placed. (*b*) Corrected position; spine straight, and the pillows placed firmly and horizontally behind the back.

FIG. 9.—Absence of chest deformity following left pneumonectomy for cystic bronchiectasis.

patient and staff, giving a measure of progress which, if not exact, is at any rate comparative, and along with this a routine clinical examination must be made.

Chronic pleural infections are liable to be followed by secondary anæmia, which may require treatment by drugs or even transfusion. It is, of course, important for the medical staff to encourage patients but at the same time to be firmly in control of their activities. It is easy to become casual in the case of prolonged illness, and it requires considerable effort from all parties concerned to maintain the necessary degree of enthusiasm and drive that should carry the patients through from their illness to a stage when they are virtually fit to return to the outside world and their former occupation.

A routine follow-up which includes radiological investigation is an important part of the control after the patient has left hospital.

On returning home the tendency to give up breathing exercises, or to adopt a faulty posture, is always there, and patients can be very like children who, under supervision, are admirably behaved, but when out of sight of their mentors tend to do the wrong things.

The return of the patient from hospital to his own or some other occupation is an interesting and critical feature as the end-result of our efforts in rehabilitation. In our own cases details have been handled by Dr. MacPhail.

Dr. William M. MacPhail: The essence of rehabilitation is good treatment. It is just good treatment made more complete and carried to its logical conclusion in restoring function as fully as possible and restoring the individual concerned to the working life of the community.

A self-contained speciality, such as a thoracic unit, provides an excellent opportunity for the essential team-work. Within the bounds of the unit there is ideal opportunity for co-operative work by the team of surgeon, physician, nursing staff and ancillary services. These ancillary services fall into three groups:—

(1) *Physiotherapists.*—Their work is so much a part of functional and indeed, mental, restoration after thoracic surgery, that the non-use of physiotherapy almost amounts to malpraxis in these days.

(2) *Occupational therapy* fulfils a useful purpose in arousing interest and initiative in patients who have had a long and discouraging illness. There should be more occupational therapy of a technical character, particularly for male patients, and the educational aspect of occupational therapy should be better developed. Along the educational line, we do a little at present, with the aid of correspondence courses, but to benefit fully from this the patient really requires some informed help and supervision. It would be more satisfactory to have in the hospital the services of a visiting educational officer. This is a very likely development of great value. Another possibility is the use of any near-by technical school or college where ambulant patients could there attend classes and receive useful technical training.

(3) *Almoners.*—As Mr. Sellors has pointed out the actual surgical operation itself is merely an incident in the course of hospital treatment of a given case. But in relation to the whole life of the individual concerned the hospital treatment is merely an incident. In order to appreciate the patient's difficulties during the time of illness and in order to make useful provision for the future, it is necessary to be intimately acquainted with the past. This is the great task of the almoners' department, and without their ceaseless interest and vigilance our rehabilitation programme would halt very badly.

The foregoing remarks apply to the rehabilitation of all patients undergoing treatment in a thoracic surgical unit. The majority of patients do not present a special problem with regard to their settlement in work. They return to their own occupation, or to their own homes if they are housewives.

With a number of patients, however, there is such a special problem in regard to employment, whether it be return to former employment on modified terms or finding a new job, or the taking up of an entirely new occupation. In regard to these cases presenting this problem of reorientation of life and of re-employment, I would like to make the following six suggestions:

(1) The approach to each case must be the individual approach. This is not a matter which can be handled by any mass tactics, or failure is certain. Each patient must be an individual study and must be constantly guided and helped till a satisfactory resettlement has been achieved.

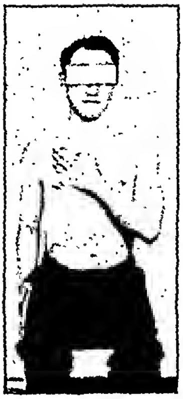

FIG. 3.

patient and staff, giving a measure of progress which, if not exact, is at any rate comparative, and along with this a routine clinical examination must be made.

Chronic pleural infections are liable to be followed by secondary anæmia, which may require treatment by drugs or even transfusion. It is, of course, important for the medical staff to encourage patients but at the same time to be firmly in control of their activities. It is easy to become casual in the case of prolonged illness, and it requires considerable effort from all parties concerned to maintain the necessary degree of enthusiasm and drive that should carry the patients through from their illness to a stage when they are virtually fit to return to the outside world and their former occupation.

A routine follow-up which includes radiological investigation is an important part of the control after the patient has left hospital.

On returning home the tendency to give up breathing exercises, or to adopt a faulty posture, is always there, and patients can be very like children who, under supervision, are admirably behaved, but when out of sight of their mentors tend to do the wrong things.

The return of the patient from hospital to his own or some other occupation is an interesting and critical feature as the end-result of our efforts in rehabilitation. In our own cases details have been handled by Dr. MacPhail.

Dr. William M. MacPhail: The essence of rehabilitation is good treatment. It is just good treatment made more complete and carried to its logical conclusion in restoring function as fully as possible and restoring the individual concerned to the working life of the community.

A self-contained speciality, such as a thoracic unit, provides an excellent opportunity for the essential team-work. Within the bounds of the unit there is ideal opportunity for co-operative work by the team of surgeon, physician, nursing staff and ancillary services. These ancillary services fall into three groups:—

(1) *Physiotherapists.*—Their work is so much a part of functional and indeed, mental, restoration after thoracic surgery, that the non-use of physiotherapy almost amounts to malpraxis in these days.

(2) *Occupational therapy* fulfils a useful purpose in arousing interest and initiative in patients who have had a long and discouraging illness. There should be more occupational therapy of a technical character, particularly for male patients, and the educational aspect of occupational therapy should be better developed. Along the educational line, we do a little at present, with the aid of correspondence courses, but to benefit fully from this the patient really requires some informed help and supervision. It would be more satisfactory to have in the hospital the services of a visiting educational officer. This is a very likely development of great value. Another possibility is the use of any near-by technical school or college where ambulant patients could there attend classes and receive useful technical training.

(3) *Almoners.*—As Mr. Sellors has pointed out the actual surgical operation itself is merely an incident in the course of hospital treatment of a given case. But in relation to the whole life of the individual concerned the hospital treatment is merely an incident. In order to appreciate the patient's difficulties during the time of illness and in order to make useful provision for the future, it is necessary to be intimately acquainted with the past. This is the great task of the almoners' department, and without their ceaseless interest and vigilance our rehabilitation programme would halt very badly.

The foregoing remarks apply to the rehabilitation of all patients undergoing treatment in a thoracic surgical unit. The majority of patients do not present a special problem with regard to their settlement in work. They return to their own occupation, or to their own homes if they are housewives.

With a number of patients, however, there is such a special problem in regard to employment, whether it be return to former employment on modified terms or finding a new job, or the taking up of an entirely new occupation. In regard to these cases presenting this problem of reorientation of life and of re-employment, I would like to make the following six suggestions:

(1) The approach to each case must be the individual approach. This is not a matter which can be handled by any mass tactics, or failure is certain. Each patient must be an individual study and must be constantly guided and helped till a satisfactory resettlement has been achieved.

(2) It is essential to be thoroughly well acquainted with the home background in relation to family circumstances, domestic relationships and financial position. It is only by thorough acquaintance with this side of the patient's life that one will be able to prevent an attempt to return to work at too early a date in the course of recovery. Also it is only by close study of all the factors involved that some of the personal and family problems of the patient can be solved.

(3) Direct approach to industry: This is a particularly useful move when we are concerned with re-employment of a patient in the case of whom it is desirable that the return to work should be modified, so that to begin with the day is not too long or too heavy. One has been struck in this connexion by the generous and sympathetic attitude of employers in industry or of personnel managers in large concerns. They are ready to be helpful and there is no question that they are interested and stimulated by personal approach through the almoning services. Better still, as a means of arousing interest, is a visit or a letter from a medical officer concerned with the patient's welfare and future employment.

(4) Ministry of Labour and National Service: The D.R.O.—Disabled Resettlement Officer from local Ministry of Labour Office—is available to interview patients in hospital to help in obtaining employment, and to arrange training for those who require to take up a new occupation. They too are able to provide information regarding the Disabled Persons Employment Act and the register of Disabled Persons. The best use will be made of its possibilities if the almoner and surgeon in charge of the case can unite in presenting to the Ministry of Labour official a picture of what the patient is able to do in the way of work, and a picture of the sociological circumstances.

(5) Voluntary agencies: It is desirable that all concerned with the welfare of problem patients should be familiar with the various voluntary agencies—and they are many—from which assistance can be invoked to meet particular difficulties. Almost invariably one or other of these voluntary agencies will be found invaluable in filling in gaps not covered by the usual official means.

(6) Follow-up: It is very important that the follow-up of ex-patients should be close and intensive, and it is very important that it should have that personal quality referred to as essential in (1). The follow-up is of supreme importance in making sure not only that the patient has obtained employment, but also that the work is within his capacity and suited to the nature of the disability. Apart from this quite obvious usefulness for the individual patient, it is of greatest value in building up our own knowledge and experience. Only by adequate follow-up and study of its findings can we learn how to obviate or to surmount difficulties.

In conclusion, let me refer again to the Disabled Persons Employment Act. This is one of the most revolutionary pieces of social legislation ever introduced, and I doubt if its far-reaching implications are quite properly understood. It will probably take about ten years before we find that the Act is properly worked so that it is the useful piece of legislation that I am sure it is destined to become. The Ministry of Labour will then indeed be worthy of the second part of their official designation which describes them as Ministry of National Service.

As medical men we must do our best to help in the development and the working of the Act, and here we have no small contribution to make to its success. There is another aspect of this Act which has an interest for physicians and surgeons. If properly used it should provide the ideal follow-up, the follow-up which will give us exact information as to the functional usefulness of our patients.

I have referred to this Act as a revolutionary measure. It is indeed outstanding in this regard among the many revolutionary happenings of recent years. I would suggest that we as a profession must also be ready to change. An essayist in the eighties of the last century, referring to men and classes of men who stood out from among their fellows, singled out the medical man as a member of a professional class almost always outstanding. I doubt if a writer on this theme would be justified in saying the same to-day. There is little doubt that as a profession we do not hold the place in the life of the community which we held at the end of the last century. If we are to regain our place as a profession in the community, then I am sure that we must be ready to leave our consulting-rooms and operating theatres and make our way to the market-place, that we must be ready to make friends with industry and that we must adapt our attitude as a profession to a rapidly changing age.

Analysis of Function

By H. Ernest Griffiths, C.B.E., M.S., F.R.C.S.

The selection of the man for the job and the job for the man is a problem which only in the last fifty years has begun to emerge as an exact science.

The industrial psychologist and the time and motion engineer began to develop their technique in a world where man-power was plentiful and labour relatively cheap and when, therefore, the physically disabled were at a discount. It very early became apparent to these research students that success and failure at work resolved themselves into questions of dexterity, temperament and fatigability—or, as the foreman would put it, clumsiness, carelessness and laziness.

Now, in the good old days, before honest toil was complicated by labour managers, psychologists, motion teams and whatnot, the foreman—that rugged child of Nature—hired and fired to the measure of his own yardstick. There was a time (I had almost quoted Goldsmith) before the Industrial Revolution cursed the community with repetitive movement, when production was in the hands of craftsmen working with simple tools but with a skill that had been acquired during long years of apprenticeship. The craftsman was a man of many parts, skilled not only in one aspect of the job, but in the whole trade, and therefore able to devise ways and means to surmount difficulties as they arose. Time and training were both on his side and the many-sidedness of his craft permitted a physical adaptability which might not be possible in the stereotyped jobs so common in modern industry. With the development of the machine tool complicated jobs were broken down into a series of simple operations and craftsmen gave place to teams of semi-skilled machine operators and assemblers.

The development of specialists in relatively simple jobs coupled with the greed for speed, focused a spotlight on those defects in the human mental make-up which meant all the difference between success and failure—dexterity, temperament and fatigability.

The foreman's method of selection by trial and error took no account of the facts that man-power was plentiful, whereas machines were precious and time was golden; industry just could not afford to train unsuitable persons for a technique which they could never master or, worse, risk delay in an operation or damage to a precious machine, possibly to be clogged up with a human limb.

It became imperative, therefore, that methods should be devised for pre-selection of units from the mass of available human material capable of giving the maximum of production with the minimum of waste. And so arose the industrial psychologist, and his opposite number the time and motion engineer, with selection tests, therbligs, process charts, and many other devices. These twin sciences have already to their credit immense achievements not only in the speeding up of production, but in improving working conditions and in devising ways and means of accident prevention.

But in no field of research has obscurity of a forest by trees been more pronounced. Just as the whole of logic is founded on the assumption "I am", so industrial psychology and motion engineering have been built on the assumption of the able-bodiedness of man. This acceptance of the universality of able-bodiedness did not, of course, imply that all men were equal or that there were not great variations in physique.

Able-bodiedness is a matter of physical function, not of shape, size or stature, and physical functional analysis is the determination of the coefficient of able-bodiedness, but physical function is the expression of thought through muscular action. It follows, therefore, that a complete analysis of physical function in any human being would be as impossible of achievement as the tale of his every thought. A practical analysis must, therefore, be attempted within certain limits. When I first used the phrase "Physical functional analysis" many years ago I was concerned solely with the fitting of the disabled into industry and was attempting to assess only those functions which would be in common use in industrial processes. Obviously I had to go to industry before coming back to man and I started to compile an elaborate list of functions which were performed at work such as, reaching, striking, carrying, screw-driving, &c., a study of these functions showed that many of them were composite and could be resolved—thus, screw-driving as generally understood, became grasping, pushing, turning. Finally, a comparatively short list of ordinary functions in industry was compiled and not all of these needed to be split into their ultimate components, e.g. cutting with scissors, humping, striking.

Let us examine "striking" a little further: a simple analysis of the physical effort made in striking with a hammer would show that the hammer is first pushed upwards against gravity and then pulled down so that the act of striking is resolved into pushing and pulling (remember the instruction you have had from your golf professional—pull with the left arm).

Some physical analyses, I think perhaps the majority, are content to leave out striking, holding it covered by its components, pushing and pulling. This is an error which can only be accounted for by the assumption of able-bodiedness. The average man can push a truck and pull a rope and push and pull a hammer, but consider the man with the old ununited fracture of the scaphoid, such a man can push a truck and pull a rope but he cannot push and pull a hammer. . . . Why? First, the obvious answer is that in striking he jars his wrist causing movement between the fragments of the scaphoid or disturbance in the surrounding soft parts. But an analysis of the three functions will show that in pushing a truck, as in pulling a rope, the wrist and carpal joints are held fixed by muscular action throughout the whole operation, whereas in striking with the hammer the wrist only becomes fixed at the moment of impact when the grasp tightens. Striking, therefore, is something more than the two simple acts of push and pull; there is a regular sequence of efforts—push, pull, squeeze—and I use the word "squeeze" here to illustrate increasing the effort of grasp which is itself a constant in all the processes under review. Unless this sudden squeeze is fully appreciated there would be difficulty in explaining the occurrence of tenosynovitis in the forearms of workers whose muscles are not trained to the use of a hammer.

An analysis of physical function is a primary concern of the motion engineer but the analysis considered from a physiological point of view is of an empirical type. Take, for example, the everyday task of polishing a floor: if you are inexperienced in housework—as I was before the war emergency turned me into an expert—perhaps you achieve your object on hands and knees by rubbing back and fore with a polishing rag. But this method would not find favour with the motion engineer (much less your wife): in his analysis he would show that at the commencement of the operation the polishing rag had to overcome inertia and acquire momentum; that the *momentum had to increase to a maximum* and then slow down to a full stop, and that on the reverse stroke inertia again had to be overcome, momentum acquired and quickened and slowed, thus causing loss of time and an immense waste of energy, both in overcoming inertia and in retarding momentum. He would point out that if a circular motion is used instead of a back and fore action most of the lost time and energy is saved, but the motion engineer has assumed able-bodiedness and therefore the ability to change from simple back and fore movement to one of rotation with all its increased problems of joint movement and muscle co-ordination. There is no doubt that experience has shown that the circular motion in hand polishing is much more successful than the back and fore. The first consideration has been the end-result, the polished surface; the time-and-motion study has shown additional reasons in the economy of time and effort.

It is now necessary to study some of the problems of physical effort in polishing with a circular or perhaps somewhat elliptical motion. The industrial psychologist could tell you that the great majority of people when polishing use a motion which is counter-clockwise with the right hand and clockwise with the left hand. Of course there are reasons for this and here are two of them: the flexors of the arm are stronger than the extensors and the power of pull is greater than that of push; in the act of polishing some of the weight of the body is used to maintain contact between the polishing cloth and the floor. The weight of the body is not evenly distributed throughout the stroke, the maximum is used at the moment of maximum physical effort and if this is also at the time when the polishing hand is nearest the centre of gravity of the body, balance is maintained with the minimum of effort. Now, consider the possibility of polishing with the right hand with a clockwise motion: if the maximum weight is to be distributed near the centre of gravity then the maximum effort must be in the push stroke, admittedly weaker than the pull stroke; or alternatively if the maximum weight is to be taken during the pull stroke, well, then it is distributed outside the centre of gravity. The arguments which I have deduced for right-hand polishing in a counter-clockwise motion are obviously applicable to left-hand polishing with a clockwise motion.

One might say that in polishing a floor the right biceps and pectoral muscles come in for a fair share of the work and that, also, the semicircular canals and postural reflexes are all mixed up in the problem. And so what of the charlady who has had a radical mastectomy or who suffers from Ménière's disease?

In this analysis of the effort produced in polishing although we started with the consideration of pull and push, we have been led to the consideration of the effort of maintaining balance. Balance is the ultimate triumph of the postural reflex and needs the functions of the organs of balance or possibly the alternative functions of sight, touch or hearing, plus the integrity of a complicated reflex arc and finally the muscle power to maintain the required position.

The able-bodied person can naturally maintain his balance without effort or thought in normal industrial processes; without conscious effort because as has already been stated, balance is the result of postural reflexes built up of joint sense, the stretch reflex, tonus and other things which are entirely subconscious; but a physical functional analysis of a disabled person may bring to light some physical defect which throws this complicated system out of gear; his employment, therefore, in industry is jeopardized.

Concussion is fairly common amongst dock workers but there are few jobs on the wharf that come strictly within the definition of light work; amongst them, however, is that of banks-man who signals to the crane or winch driver to direct him in the placing of a load. Such a job might be ideal for a man who suffered headache and was better in the open air than indoors. But before placing him it would be better to know whether looking up made him liable to lose his balance and fall in the dock.

I have been trying by simple examples to show the need for physical functional analysis in the placing of the disabled person and that this analysis must play a big part in the future in the work of the industrial psychologist and the motion engineer.

Physical functional analysis is concerned not with the method of performance but with the physical requirements that are necessary to carry out that method or an alternative method calculated to produce the same result. If one is concerned solely with the first part of the definition, namely the carrying out of a particular method, and not the consideration of alternative methods, then it may be possible to consider a limited functional physical analysis as applied to definite anatomical regions of the body; but if alternative methods are to be considered then the function of the body as a whole must be the subject of study. Again, a very clear distinction must be made between physical function and mental function. Take, for example, writing: the action of holding and propelling a pen across paper is entirely physical but the ability to control the pen so that it forms letters is a mental process and once the power to write has been acquired the writing skill is not lost because the usual means of applying that skill are lost, any more than would be the skill to read. If a man learns to read by sight and then becomes blinded he has not lost the power but only the means to read; alternative means can be provided through touch and when he is taught Braille he is only taught to apply a new means to a skill he already possesses.

After a physical function has been defined the analysis must take note of the quality of that function, and here again the distinction between mental and physical function may be difficult to define and in some respects they may be shown to be reversed in the disabled as compared with the able-bodied. As an example, fatigability in the able-bodied is primarily a psychological problem, the degree of bodily fatigue in a process is directly proportionate to the psychological effort involved but this is not necessarily true where the balance of opposing muscles has been upset by disease or possibly injury. Take, for example, the poliomyelitis case with weakness of the leg muscles, or the man with internal derangement of the knee and wasting of the vastus internus muscle: in this latter case the power of sustained tonus may be diminished to such an extent that the knee is apt to give way and balance and security are affected.

Attempts have been made to subdivide physical function into certain constituent parts. McBride suggested quickness, co-ordination, strength, security, endurance, safety, physique—by physique he meant outward appearance, holding that deformity might have an adverse effect upon the morale of the man as well as on the chances of his employment. He has endeavoured to estimate percentage loss of each one of these components and so to arrive at a percentage loss of function as a basis for compensation for industrial injuries. Kessler and others have criticized his methods and have pointed out the many fallacies that must creep in.

Able-bodiedness is a matter of physical function, not of shape, size or stature, and physical functional analysis is the determination of the coefficient of able-bodiedness, but physical function is the expression of thought through muscular action. It follows, therefore, that a complete analysis of physical function in any human being would be as impossible of achievement as the tale of his every thought. A practical analysis must, therefore, be attempted within certain limits. When I first used the phrase "Physical functional analysis" many years ago I was concerned solely with the fitting of the disabled into industry and was attempting to assess only those functions which would be in common use in industrial processes. Obviously I had to go to industry before coming back to man and I started to compile an elaborate list of functions which were performed at work such as, reaching, striking, carrying, screw-driving, &c., a study of these functions showed that many of them were composite and could be resolved—thus, screw-driving as generally understood, became grasping, pushing, turning. Finally, a comparatively short list of ordinary functions in industry was compiled and not all of these needed to be split into their ultimate components, e.g. cutting with scissors, humping, striking.

Let us examine "striking" a little further: a simple analysis of the physical effort made in striking with a hammer would show that the hammer is first pushed upwards against gravity and then pulled down so that the act of striking is resolved into pushing and pulling (remember the instruction you have had from your golf professional—pull with the left arm).

Some physical analyses, I think perhaps the majority, are content to leave out striking, holding it covered by its components, pushing and pulling. This is an error which can only be accounted for by the assumption of able-bodiedness. The average man can push a truck and pull a rope and push and pull a hammer, but consider the man with the old ununited fracture of the scaphoid, such a man can push a truck and pull a rope but he cannot push and pull a hammer. . . . Why? First, the obvious answer is that in striking he jars his wrist causing movement between the fragments of the scaphoid or disturbance in the surrounding soft parts. But an analysis of the three functions will show that in pushing a truck, as in pulling a rope, the wrist and carpal joints are held fixed by muscular action throughout the whole operation, whereas in striking with the hammer the wrist only becomes fixed at the moment of impact when the grasp tightens. Striking, therefore, is something more than the two simple acts of push and pull; there is a regular sequence of efforts—push, pull, squeeze—and I use the word "squeeze" here to illustrate increasing the effort of grasp which is itself a constant in all the processes under review. Unless this sudden squeeze is fully appreciated there would be difficulty in explaining the occurrence of tenosynovitis in the forearms of workers whose muscles are not trained to the use of a hammer.

An analysis of physical function is a primary concern of the motion engineer but the analysis considered from a physiological point of view is of an empirical type. Take, for example, the everyday task of polishing a floor: if you are inexperienced in housework—as I was before the war emergency turned me into an expert—perhaps you achieve your object on hands and knees by rubbing back and fore with a polishing rag. But this method would not find favour with the motion engineer (much less your wife): in his analysis he would show that at the commencement of the operation the polishing rag had to overcome inertia and acquire momentum; that the momentum had to increase to a maximum and then slow down to a full stop, and that on the reverse stroke inertia again had to be overcome, momentum acquired and quickened and slowed, thus causing loss of time and an immense waste of energy, both in overcoming inertia and in retarding momentum. He would point out that if a circular motion is used instead of a back and fore action most of the lost time and energy is saved, but the motion engineer has assumed able-bodiedness and therefore the ability to change from simple back and fore movement to one of rotation with all its increased problems of joint movement and muscle co-ordination. There is no doubt that experience has shown that the circular motion in hand polishing is much more successful than the back and fore. The first consideration has been the end-result, the polished surface; the time-and-motion study has shown additional reasons in the economy of time and effort.

It is now necessary to study some of the problems of physical effort in polishing with a circular or perhaps somewhat elliptical motion. The industrial psychologist could tell you that the great majority of people when polishing use a motion which is counter-clockwise with the right hand and clockwise with the left hand. Of course there are reasons for this and here are two of them: the flexors of the arm are stronger than the extensors and the power of pull is greater than that of push; in the act of polishing some of the weight of the body is used to maintain contact between the polishing cloth and the floor. The weight of the body is not evenly distributed throughout the stroke, the maximum is used at the moment of maximum physical effort and if this is also at the time when the polishing hand is nearest the centre of gravity of the body, balance is maintained with the minimum of effort. Now, consider the possibility of polishing with the right hand with a clockwise

The pure scientist may wish to see each one of these composite functions split up into its ultimate anatomical, physiological, and psychological components; he will want to discuss postural reflexes, conditioned stimuli and so on; and it is all a fascinating and useful study which has an important bearing on methods of medical and surgical treatment, on investigations of conditions and ways of employment, and of the cause and the prevention of accidents. I have referred to some of these problems elsewhere (Hunterian Lecture, "Treatment of the Injured Workman", *Lancet*, 1943 (i), 729) but I am limiting this analysis to a point at which I feel that the expert's analysis will be intelligible to the layman and, therefore, usable by one whose business it is to select the man for the job. In this sense, therefore, the following list may be regarded as one of primary functions:

> Balancing, running, jumping, climbing, kneeling, stooping, crouching, reaching, throwing, lifting, pulling, pushing, striking, carrying, humping, handling, fingering, cutting with scissors, feeling.

You may also think that turning should be added as something distinct from handling and possibly you may wish to include other actions.

Feeling is dependent upon the sense of touch and, of course, no analysis that does not include an intelligible note on the other special senses can be complete, e.g. sight. In general employment it is sufficient to know whether a man can see reasonably well at a distance and whether he can see reasonably small print and also perhaps whether it is necessary for him to wear glasses. It is true that in certain special industries good colour vision is necessary and in some very acute sight; in such industries sight selection tests are necessary and as these cannot be carried out satisfactorily by the ordinary general practitioner, I have not thought it necessary to include them in this primary functional analysis. Similarly, specific tests for hearing and smell and taste are not included.

The human stresses and strains from industrial effort vary enormously with the circumstances in which the effort is made. Let us go back to the sack of potatoes. Supposing the sack is in the middle of a large field; the workman will be exposed to the vagaries of the weather and this may not suit his rheumatism, his bronchitis, or his thrombo-angiitis obliterans. The situation is perhaps so isolated and open as not to be borne by the man with agoraphobia. But perhaps the potatoes are stored in a warehouse. As the sacks are moved the air soon becomes thick with dust to the discomfiture of the chronic asthmatic or the man with ectropion. And so in addition to the place of work the conditions of work become important—dust or damp, extremes of heat or cold, &c.

Certain jobs are fraught with special risks—the window cleaner may fall from a height, the tar sprayer develop cancer of the skin, or the radiographer an aplastic anæmia and so on. Every able-bodied person doing a job is exposed to the risk appertaining to that job but a physical examination of a particular individual may disclose a morbid condition which increases the normal risk. A minor degree of instability in the knee-joint may permit the man to run, climb and jump, and yet it may be just sufficient to interfere with the maintenance of balance on a narrow ledge, which is essential to the safety of a window cleaner.

Thus, the physical functional analysis, whilst listing the possession of certain faculties used in the normal course of industry, would be failing in its purpose of demonstrating employability unless it also qualified its list by indicating any adverse factors in the bodily or mental make-up of the workman which would render him unsuitable for employment in circumstances of exceptional environmental conditions.

Physical functional analysis should be presented as an exact piece of work with the very minimum of medical opinion and the maximum of physiological fact. It should not be attempted unless the physician is prepared to make a thorough routine examination of his patient. As we are dealing now with the practical problem of fitting the able-bodied and the disabled into industry this routine examination must be understood as one that can be undertaken by a painstaking general practitioner or industrial medical officer. I know there are exceptional cases in which the opinion of a specialist may be needed but these *are* exceptions.

After the examination comes the recording of the analysis and this *may* be done as a medical report. Suppose it reads: "This man had a Pott's fracture and is now fit for light work". This would not convey much of your expert knowledge of the man's condition to the layman. The purpose of the physical functional analysis is the selection of the man for the job and this is a task for industry, not medicine. Your analysis, which is a purely medical affair, is of primary importance, but it is not the only important factor in placing the man in work. Do not forget the industrial psychologist and his selection tests, or the labour manager, or the manager of the machine shop—this latter would not have reached his position unless he was something of a psychologist; it may be his opinion that the girls

Perhaps the chief fallacy of this method is that it focuses attention upon local physiological action rather than the result of that action. The estimate of function is not measured in the angle through which a joint can be flexed but in the power of purposeful effort that may be achieved through this action. This power of purposeful action depends upon so many factors beside the flexion of the individual joint that in considering it the investigator is invariably forced back to the consideration of the body as a whole.

The scale, as well as the tale, of human physical function will vary enormously in different individuals. In a particular group all may be able to lift but whereas one can lift 10 lb., another 20 lb. and another 100 lb., the ability to do a particular job may depend on the power to lift 50 lb. or more; thus, the functional analysis recording the ability to lift without some indication of the power is of little value. Suppose the job to be one of lifting sacks of potatoes weighing ½ cwt. 4 ft. from the ground to the back of a lorry; this, of course, is not simply a question of strong arms. Consider how the job is done: the workman lowers his arms to grasp the sack, by the simple expedient of bending his knees and hips—the expert hardly flexes the spine at all—the lift is initiated by extension of the knee-joints and the hip-joints and is then assisted by simultaneous flexion of the elbow-joints and abduction of the shoulders (for the sake of simplicity I am omitting reference to the movement of other joints, such as the mid-tarsals). Given, therefore, a physique with sufficient power in the muscles which control these joints, the workman is capable of doing the work in question—but that is only on the assumption of able-bodiedness. Suppose now that this powerful fellow has a diseased heart: he might have the physical power to perform the task but not the recuperative power to withstand the consequences; such a man is unfit for the work in question and yet his unfitness has not been disclosed by the movement of lifting as we have considered it so far. We must carry the study a little further and consider the trunk in relation to the limbs. At the moment of initiation of the lift and generally throughout the lift, respiration is inhibited: the primary reason for this is to fix the ribs and therefore give points of fixed attachments for the muscles controlling shoulder movement. You will remember that only man and his kind and the cat and her kind have this capacity and therefore they are the only animals that can strike an effective blow from the shoulder. Holding the breath for a moment or two may have no great effect on the ordinary man, but consider one suffering from chronic emphysema—you can see his face getting blue with every effort and before long he has to interrupt his lifting to rest because he cannot compensate for holding his breath by taking a few deep breaths. He is therefore not fit for the job because he has no power of endurance in that particular form of work. This man might have been employed on equally arduous work humping the sacks from the lorry to the store because the action of humping demands regular breathing. Our study has disclosed so far why the ribs are fixed and the breath is held but not how it is done. I need hardly remind you that amongst other happenings there is contraction of the diaphragm and of the great muscles of the abdominal wall, including the rectus, external and internal obliques, transversalis and quadratus lumborum. The first three of these are flexors of the spine; any attempt at faulty lifting by using the erector spinæ muscles to extend a flexed spine will be against the resistance of these flexors and therefore inviting a "strained back". This is an important consideration in giving a man with a stiff knee a job involving lifting from the ground level.

But there is another consequence of fixing the lower ribs. As the diaphragm is forced down and the other muscles of the abdominal wall contract, the pressure within the abdominal cavity rises and any tendency to hernia may be exposed.

We have made a superficial study of the behaviour of the limbs, trunk, heart and lungs during the act of lifting a 56 lb. sack, but have not considered the mechanics of the whole movement. I will only draw attention to the subject of balance without which the whole effort fails.

It should now be apparent that in making a physical functional analysis as a means of determining employability or capacity for particular work, there are certain considerations of the general bodily state which must take precedence over the determination of the ability to perform certain specific evolutions.

First comes stamina: has the man the power of physical endurance necessary to work through the hours that are expected of him—the hardest man to place in industry is the man who can only work broken time. Next to this comes the estimation of power, the ability to withstand the required physical strain, say, one equivalent to the lifting of a 56 lb. weight. Then comes balance or the ability to maintain the body in the required positions.

Only when the general bodily state has been determined can we move on to the delineation of other faculties. At the outset of this more detailed study we must resign ourselves to the acceptance of certain complicated movements as though they were not capable of being resolved into simpler actions; e.g. running, jumping, climbing.

was opened. I was told that as a surgeon I was not capable of recognizing neurosis. My reply was that perhaps there might have been a patient in whom I had not noticed the neurosis but my patient did not notice it either, and he had gone back to work and his employer had not noticed it, and at the end of the week he had taken home a full pay packet and his wife had not noticed it; and so what the . . . ! But nevertheless there are certain obvious and important defects which may be grouped under "nervous state" and which will affect employability, e.g. stammer, tremor and fits.

Normally vision for the purposes of ordinary work implies the ability to see at a distance and to perform reasonably fine work as in reading ordinary newspaper print. The loss of sight in one eye, provided the other eye be normal, has very little effect upon employability except in certain occupations where standards of physical health are laid down as conditions of employment. The routine examination is quite sufficient to fill in the section on vision as it is for the section on hearing.

On page 6-G three sections are devoted to environment including place of work, working conditions and special hazards. Almost each one of the special conditions recorded has some disadvantage for the able-bodied person. Therefore they only need comment if such conditions would cause special hardship to the individual concerned, e.g. the gastric case may be at a disadvantage if there is no canteen at his place of work where he can get reasonable food or if he has to engage in shift work and so upset the routine of normal feeding. The information under this heading of environment is of great importance to the D.R.O. and it is precisely this information that is omitted in the great majority of written medical reports.

What may be termed the true analysis of function ends on page 6 but on page 7 there is a short form of medical certificate dealing with prognosis and treatment. In this connexion H-3 has already been answered.

I hope that by now I have convinced you that if it falls to your lot to submit to the D.R.O. an opinion on the capacity for work of one of your patients the easiest, quickest and most comprehensive method of doing so will be by filling in this report form—a task which should take you well under three minutes.

The major use to which a functional analysis can be put in the employment of the disabled person is in determining those limits within which he may perform ordinary work by the ordinary methods. A second important use is in supplying information for the selection of alternative methods in performing ordinary work, e.g. driving a screw into a hole in wood. If the workman is watched carefully it will be seen that: (*a*) he reaches out with his left hand and selects a screw from a container, often without looking; (*b*) he picks up the screwdriver with the right hand; (*c*) places the screw in position with the left hand, looks at the head of the screw and places the screwdriver in position; (*d*) with his eye on the screw he exerts pressure through the screwdriver and at the same time rotates the driver in a clockwise direction.

All these might have been expressed in terms of functional analysis as: (*a*) reaching, feeling, fingering; (*b*) handling, lifting; (*c*) seeing, handling; (*d*) seeing, pushing, handling (or turning).

Now the first analysis with its reference to right and left hands and to the eyes suggests that the work of driving a screw into a hole is necessarily a two-handed job for a man with good eyesight. The second analysis only details function and makes no reference to the means of its performance. Reaching, feeling, fingering, handling, lifting, seeing, pushing, turning; with these functions grouped together thus it becomes apparent at once that here is scope for the employment of substitute functions. Take, for example, feeling and seeing; these are complementary to each other; the blind man can drive in a screw perfectly well because he uses feeling instead of his sight, and the man who has lost the sensory nerve to the fingers can select and pick up a screw if he looks at it. This work may be done by a blind man or a man who has lost the feeling in his fingers; it may be done by a one-armed man or even the man with no arms if fitted with suitable appliances and if able to see.

Perhaps I have already said enough to show how great a difference there is between the analysis of function and a purely physical examination and also to show how the one can never be matched with the other. Physical examination means the regional study of the body, whereas functional analysis must mean the study of the body as a whole. It is for this reason that these schedules of disabilities that are so constantly used as methods of assessment in pensions schemes fail so completely when used to indicate how much the individual has lost or how much he falls below able-bodiedness as the result of his scheduled disability. The schedule is a scale of physical disability; an analysis of function is the study of the man.

on a particular machine won't keep their minds on the job if the new tool-setter, however capable, is a red-head.

Much of the value of your analysis will depend on the way in which it is set out and therefore on the way in which it makes available and intelligible to the lay mind the result of your research—and each medical examination you make is an important piece of research. An outline for a medical report in the form of a functional analysis, the D.P.1, is issued by the Ministry of Labour and National Service and is intended to help the medical examiner to furnish all the medical data which the D.R.O. may require before recommending a disabled person for employment in a particular industry.[1] This form was the product of the labour of the Hooper Committee, a joint committee set up by the Ministries of Labour, Health and Pensions. It is not claimed that the form is perfect, experience in its use may result in minor or important modifications; or it may be scrapped. Experience has already shown that whereas the ordinary written report of a doctor may enable the D.R.O. to decide whether a man is suitable for registration as a disabled person, it is quite valueless as a guide to his employability.

This form at first sight appears to be not only complicated, but alarming; but if it is once read through, which may take you five whole minutes, I think it will be appreciated that it is really a great time- and labour-saving device. It does nothing to shorten the medical examination. As I have already stated the thoroughness of the medical examination is the first essential of any functional analysis: but when the examination has been made it saves both time in writing and thought in composition. Finally, it is almost certain to obviate many sins of omission.

The doctor's share in the filling of the D.P.1 starts on page 2 with the diagnosis and, if he knows it, the M.R.C. Code No. This page is unessential for the prime purpose of the report but is useful for research and follow-up.

Page 3 is a functional analysis of the individual as a whole given in the broadest sense and enables the D.R.O. to make his preliminary classification. The whole page can be filled up in five seconds by making five ticks, provided there are no special circumstances requiring a short note in paragraph 2. In practice paragraph 2 on this page does not need filling up in 1% of the cases. Now the five ticks you have placed will have drawn for the D.R.O. a picture something like this. Here is a man who is capable of working a 44-hour week (full time) provided that his place of work is within a mile of his home (restricted travelling) and that he is not called upon to exert a physical strain that is greater than one which would be imposed upon him by the lifting of a 56 lb. weight (medium). He is capable of doing work that involves walking about but he can only work indoors. If you had been writing the report I wonder if you would have thought it necessary to give all this information and, if you had, whether you could have done it in five seconds; and yet it has enabled the D.R.O. to decide in his mind that this man must almost certainly be found employment in a factory, shop or office, and all those fields of labour like agriculture, coal-mining, shipping and transport are closed to him.

Turn now to page 4. The majority of people who are examined will possess the majority of the functions recorded on this page and therefore it is only necessary to indicate those that are lost by placing a cross in the appropriate column. Your examination will have given you the information that should be necessary to decide if a cross is indicated but if there is any doubt the easiest way of finding out is by simple trial. There may be one or two of these functions of which you are not quite certain; perhaps humping, handling and fingering may need a little explaining and they are defined upon the next page. Humping is a technical term used throughout industry for carrying a load on the back; it does not involve lifting the load into position on the back. Handling is a word used to cover those functions in the hand that do not necessarily require special dexterity, such as holding, grasping and turning. You will note that no mention is made of loss of part or all of fingers; a hand may have some mutilation and still retain good power of handling. Fingering, on the other hand, implies the dexterous use of individual fingers as in the pincer grip between the thumb and the index finger or in the use of a needle or a typewriter. Unless the examiner feels that some special comment should be made on any one of the above, this page can be filled in a few seconds.

Page 5 records the nervous state and the vision. The estimation of the nervous state is arrived at during the routine examination and does not imply or require a special psychiatric examination. I remember some time ago being very severely taken to task by a psychiatrist because I said that not a single case of neurosis had occurred in my Fracture Clinic since it

(1) THE CLASSIFICATION OF PHYSIQUE

AT the present time there are, I think, only two classifications of physique that need to be considered at length. Both these systems, as well as the one previously widely used but now obsolete, were devised by psychologists, in a sphere where one might have thought anatomists and physical anthropologists would naturally have dominated research. The first system—I do not mean to imply the first in time, because both were devised contemporaneously and independently over a number of years—the first is that of William Sheldon, published in 1940, now generally quite well known and by virtue of a later publication on temperament, something of a storm centre [1, 2]. The second is that of Sir Cyril Burt, and arose from the application to measurements of the body of the statistical technique of factor analysis, which he has been so prominent in developing as applied to mental tests [3]. A somewhat similar technique has been developed by Professor Mahalanobis of Calcutta, and is now being applied for the first time to problems of physique, in India [4]. In the United States also the factor analysis technique has been used for studying body build, most notably by Carter and Krause in California, McCloy at Iowa, and by Mullen, under the guidance of Prof. Karl Holzinger, in Chicago [36 to 39]. Though these studies have not developed as far or as clearly as have Burt's, the earliest of them preceded Burt's initial publication [35]; they have all been reported, however, in journals of very restricted circulation in this country, and have not been previously remarked here.

I have already implied that the classification of Kretschmer, which consolidated many major advances at the time of its publication, is now obsolete. This is because Sheldon's system has all the advantages of Kretschmer's, and only some of its disadvantages, besides differing from it in a very important and fundamental way. Kretschmer's fundamental mistake was the division of mankind into disparate *types*. He assumed the existence of a trimodal distribution, with large numbers of people belonging to each of his types, and some as mixtures. He failed to grasp the idea of continuously varying *components* of body build, each distributed smoothly and unimodally in the population. Sheldon began from the premise of continuous components; he writes: "The concept of types has been useful in the study of personality, but, like the poles supporting a clothes-line, it provides only end suspension for distributive classifications. As the line becomes filled, the notion of types recedes and finally vanishes altogether, perhaps submerged under a smooth distribution. The path of progress is from the notion of dichotomies to the concept of variation along dimensional axes" [1].

Sheldon began by sorting nude standardized photographs, showing front, side and back views, of 4,000 college students. Disregarding the attribute of largeness or size, he found three extremes of body build present, representing the ends of the distributions, then, of three components. Every individual had now to be assigned a place in the distribution of each component; everyone had *some* of each component in his make-up. Using a 7 point, equal-appearing interval scale, Sheldon rated each individual on each component. Thus the first extreme example was rated as 7–1–1, scoring 7, the maximum, in the first component, and 1, the minimum, in the other two. The second was 1–7–1, and the third 1–1–7. The three components were named endomorphy, mesomorphy and ectomorphy.

Dr. Frank Howitt congratulated Mr. Griffiths on his Address and said that this was an important contribution to purposeful doctoring. He drew attention to the fact that such an analysis had been in force in the Army during the latter stages of the War under the name of P.U.L.H.E.M.S. This was a functional analysis of the whole man based on the mental and physical capacity of the individual in relation to physique, strength, hearing, eyesight, mental stability, &c. A similar assessment had been made of the requirements of all the 600 odd Army trades, so that it was an easy matter for the Hollerith machine to place recruits into occupations which would appear most fitted to their potential capacities. He wondered whether some simplified form of this successful Army experiment could not be translated into civilian usage with advantage.

He also drew attention to the importance of previous training for any given job. It was unwise to assess a man's capacity for the performance of any work or movement without previously instructing him in the correct methods of its execution. Even simple tasks such as jumping, lifting and climbing are very imperfectly performed by the average individual, owing to ignorance of technique. Assessment of functional capacity should, therefore, be delayed until the opportunity of such instruction has been given.

Mr. R. E. Gomme (Ministry of Labour) said that the Ministry's experience of the form D.P.I was limited because it had not so far been used by hospitals in respect of patients discharged with some residual disability. Such experience as they had of the form was sufficient, however, to indicate its real value to the lay staffs of Employment Exchanges (the D.R.O.s) whose duty it was to advise disabled applicants on the kind of employment best suited to their disability and ability. The form gave the D.R.O. a general picture of the applicant's functional capacity and thus helped him to talk both to the applicant and to prospective employers with a certain amount of confidence. Mr. Gomme said that it was intended to use the form under the new Interviewing Scheme which it was hoped to introduce shortly and which would include an opportunity for discussion between the doctors and the D.R.O. Though there had been some criticism of the form on minor points of detail, it had been welcomed by medical members of Disablement Advisory Committees and their Panels—and so far as the Ministry was aware, by the Medical Profession generally.

Dr. Mark Hewitt (Regional Medical Consultant) began by referring to the words written by Galen in A.D. 172 that "Full employment is essential to human happiness, work is Nature's best physician."

At the moment many hospital doctors were not fully aware of the therapeutic value of work, and although they were concerned about nursing, specific treatment, non-specific treatment, physiotherapy and the like, they did not fully appreciate the important fact that full employment was the be-all and end-all of their treatment, and in view of this they were not at the moment taking full advantage of the facilities being offered for the placement of their patients in industry after treatment in hospital.

Many schemes had been formulated, especially in the United States, for job analyses and job placement. Some of the schemes had involved the drawing-up of various categories of the disabled on the one hand, with large lists of the various types of jobs for disabled on the other, but these mass placement schemes took individual personality very little into account, and would not at the moment seem to be a practical measure. He felt that the time for this type of work had not yet arrived, and placement could only be of an individual nature.

In Manchester they were attempting, in conjunction with Professor Crighton Bramwell of the Manchester Royal Infirmary, a scheme for individual job placement of cardiac patients. The unemployed cardiac patient was fully examined, an accurate diagnosis made and a therapeutic classification given according to the amount of work possible. The various jobs, i.e. the cotton and the engineering industries, were being closely surveyed and assessed for their work requirements. In co-operation with the Almoner, personal factors such as travelling, domestic circumstances, &c., would be taken into consideration, and by this means it was hoped to place this group of cases in the most suitable type of work fitted to their disability, and, more important still, to follow their progress.

The Industrial Medical Officer had an important role to play in seeing that the disabled person was satisfactorily resettled in a suitable job, and the importance could not be over-emphasized of the Industrial Medical Officer, D.R.O. and the hospital doctor working as a team in all matters where unemployed disabled were under consideration.

(1) THE CLASSIFICATION OF PHYSIQUE

AT the present time there are, I think, only two classifications of physique that need to be considered at length. Both these systems, as well as the one previously widely used but now obsolete, were devised by psychologists, in a sphere where one might have thought anatomists and physical anthropologists would naturally have dominated research. The first system—I do not mean to imply the first in time, because both were devised contemporaneously and independently over a number of years—the first is that of William Sheldon, published in 1940, now generally quite well known and by virtue of a later publication on temperament, something of a storm centre [1, 2]. The second is that of Sir Cyril Burt, and arose from the application to measurements of the body of the statistical technique of factor analysis, which he has been so prominent in developing as applied to mental tests [3]. A somewhat similar technique has been developed by Professor Mahalanobis of Calcutta, and is now being applied for the first time to problems of physique, in India [4]. In the United States also the factor analysis technique has been used for studying body build, most notably by Carter and Krause in California, McCloy at Iowa, and by Mullen, under the guidance of Prof. Karl Holzinger, in Chicago [36 to 39]. Though these studies have not developed as far or as clearly as have Burt's, the earliest of them preceded Burt's initial publication [35]; they have all been reported, however, in journals of very restricted circulation in this country, and have not been previously remarked here.

I have already implied that the classification of Kretschmer, which consolidated many major advances at the time of its publication, is now obsolete. This is because Sheldon's system has all the advantages of Kretschmer's, and only some of its disadvantages, besides differing from it in a very important and fundamental way. Kretschmer's fundamental mistake was the division of mankind into disparate *types*. He assumed the existence of a trimodal distribution, with large numbers of people belonging to each of his types, and some as mixtures. He failed to grasp the idea of continuously varying *components* of body build, each distributed smoothly and unimodally in the population. Sheldon began from the premise of continuous components; he writes: "The concept of types has been useful in the study of personality, but, like the poles supporting a clothes-line, it provides only end suspension for distributive classifications. As the line becomes filled, the notion of types recedes and finally vanishes altogether, perhaps submerged under a smooth distribution. The path of progress is from the notion of dichotomies to the concept of variation along dimensional axes" [1].

Sheldon began by sorting nude standardized photographs, showing front, side and back views, of 4,000 college students. Disregarding the attribute of largeness or size, he found three extremes of body build present, representing the ends of the distributions, then, of three components. Every individual had now to be assigned a place in the distribution of each component; everyone had *some* of each component in his make-up. Using a 7 point, equal-appearing interval scale, Sheldon rated each individual on each component. Thus the first extreme example was rated as 7–1–1, scoring 7, the maximum, in the first component, and 1, the minimum, in the other two. The second was 1–7–1, and the third 1–1–7. The three components were named endomorphy, mesomorphy and ectomorphy.

Fig. 1[1] shows three individuals fairly near the extremes. The man high in endomorphy and low in mesomorphy and ectomorphy is, speaking in caricature, spherical; a sort of globule with a round head, large fat abdomen which predominates over his thorax, and weak floppy, penguin-like arms and legs. The second is the physical training instructor caricature, with cubical massive head, muscular neck, broad and muscled chest, and thick strong muscular arms and legs. The third, again in caricature, disappears when you look at him sideways; he has a thin peaked face with a receding chin and a high forehead, a thin narrow chest and abdomen, and spindly arms and legs. Naturally, only a very small percentage of people look like this; the majority have a moderate amount of each component, and so have as their *somatotype*, as the set of 3 ratings is called, such numbers as 433, 344 or 352. The number of possible combinations of 7 things taken three at a time is 343, but the three components are not independent. They are negatively correlated, so that a high rating in one precludes to some extent high ratings in the others. Thus 771s and 555s do not exist, but 641s and 444s do. 76 somatotypes occurred in Sheldon's 4,000 pictures, and only 50 were at all common. *It must be clearly emphasized that the somatotype is not like the conception of the old fixed type, however; it merely results from making artificial discontinuities in a continuous scale.* The somatotype is a pigeon-hole into which is placed everybody who, on the continuous scales, is nearer that pigeon-hole than any other. In fact, most workers in this field now use halves on the rating scale, converting it to a thirteen-point scale, with a correspondingly larger number of smaller pigeon-holes.

One secondary point in Sheldon's classification must be mentioned here, because we will return to it at the end of this paper. It concerns the degree to which the male body resembles the female and vice versa. Sheldon calls this attribute the *gynandromorphic component*, and rates his subjects on this, again on a 7-point scale. The amount of femininity of build is not independent of the somatotype entirely, but different members of the same somatotype may nevertheless differ quite considerably in the gynandromorphic component. The man who is high in gynandromorphy has, amongst other features, large hips relative to his shoulders, a protuberance of fat above the symphysis, a fullness in the mammary area, and an approximation or overlap of the thighs when the heels are held together.

Having distinguished his somatotypes subjectively, Sheldon then put them on an anthropometric basis. The somatotype of a given individual may be found, without any element whatsoever of subjectivity, by another worker, who takes the standardized photographs, measures 17 diameters of the body from them, and consults Sheldon's tables. (At least this is theoretically so, but, so far, tables have only been published for the 16 to 20 age-group.) Thus any investigator who takes the trouble to measure his photographs may reach precisely those conclusions which Sheldon would have reached, and his results will be comparable with Sheldon's. However, the *original* scale still remains a subjectively determined one, set up by the operation of judgment of equal-appearing increments of somewhat complex stimuli. The root objection to Sheldon's system springs from this fact, that we do not know much about the nature of such scales. Consequently the further statistical manipulation of somatotype data is hazardous. A secondary, allied objection is that we are limited to making discrete jumps in our ratings across portions of the background scale: we cannot interpolate values from anthropometry with confidence, because of this uncertainty of the scale.

The factor analysis of physique, developed chiefly under the guidance of Sir Cyril Burt [5], meets both these objections. The technique is one of the forms of mathematical analysis designed to reduce to human comprehension large numbers of measurements taken simultaneously of several variables. In Burt's hands, this consists of reducing a matrix of covariances or correlation coefficients, such as may be obtained from a series of measurements on the body, to the result of the linear combination of a few other, mutually independent measures, called factors. Thus if we have three factors, A, B, and C, which together designate body build, we can describe a given individual not as measuring such and such in height, weight, leg length, head circumference, chest depth and so on, but more simply as so much of factor A plus so much of factor B plus so much of factor C. Put thus the method sounds similar to Sheldon's, and, indeed, so it is, in essence. The differences spring from the uncertainty of Sheldon's scale, and more importantly, as we shall see, from the fact that Sheldon's components are correlated, while Burt's factors are not.

We can tackle the first point by way of some of Burt's results. The analysis of his latest and most complete data [6] leads to a general factor, a main bipolar factor, and several other factors we shall discuss later. This first bipolar factor has been called the leptosome-pachysome factor by Burt, because its positive saturations are with girth and its negative with length, notably stature, leg length and arm length. Burt also worked out the multiple regression equation for this factor score, in terms of height, weight and leg length; measurements which, to within a small margin represented by a multiple correlation of 0·96, serve to estimate the factor. He was kind enough to let me have this equation in advance of publication, since I happened to possess these measurements on 50 students who had also been somatotyped anthroposcopically by Dr. C. W. Dupertuis, one of Sheldon's close associates, and myself in 1943. Fig. 2 shows the relation between estimated ectomorphy and Burt's leptosomic factor. It is quite obvious that Sheldon and Burt are measuring the same thing, perhaps in slightly different ways. Furthermore, allowing for some errors in the estimation of ectomorphy (since it was not done anthropometrically), for the fact that I had not taken leg measurements in precisely the same way as Burt's measurer, Dr. Morant, and for Burt's regression equation not being absolutely stable if other original measurements are taken, I suspect that the relationship is a straight linear one. The correlation coefficient is −·94. (There is a curious failure to assign any 3½ ratings and if some of the 4 and 4½ ratings were reduced, as this lack might reasonably indicate they should be, the correspondence to linearity would be still closer.) If this proves on further testing to be the case, then we can say that at least as far as ectomorphy is concerned, Sheldon's scale and Burt's are of a precisely similar nature [7], and that the analogue of the Weber effect did not occur, as Sheldon suggested it might have done, in his ratings [1, page 125]. (The other possibility is that the midrange ratings are somewhat inflated, as Sheldon suggests they may be.)

---

[1] *Owing to the paper shortage it is not possible to publish the figures referred to in this paper. Copies of figs. 2 to 6 can, however, be obtained from the author.*

Now this makes it immediately impossible for any other of Burt's factors to correspond with mesomorphy or endomorphy, since the factors are independent and uncorrelated and the components are not. Could we then represent Sheldon's components by two further *oblique* factors; that is, factors which are themselves correlated? Such would seem to be a possibility, at least. But a further question, I think, must arise here, and that the simple one, why bother? Is there any advantage of oblique over orthogonal factors, or any disadvantage? This is ground fought over to exhaustion by the various schools of factorists; Thomson perspicaciously remarks that "it is really impossible to decide between them (the alternative procedures) without first deciding why we want to make factorial analyses at all" [8]. This I think we are in a better position to decide, with regard to physical measurements, than the psychologists are with regard to mental ones.

Factorial analysis, like any other statistical procedure, is a method for classifying things (or, speaking more strictly, events). Now classifications depend for their use on their *usefulness*, and the most desirable classification is that which, at the time of its use, sheds most light on the relations between one set of facts and another. We must then decide what sort of classification in the sphere of physique is most useful in illuminating studies of personality. We may interject here a way of considering personality. I wish to consider the word as referring to the sum total of all the attributes of a human organism, attributes which we describe at various *levels*. These levels on which we abstract and describe personality may be roughly defined following the traditional scientific divisions—anatomical, physiological and psychological, with the last divided into levels of temperament, character, disposition, cultural behaviour and so forth. A certain amount of knowledge has now accumulated on each of these levels, but the synthesis as between one level and another still lags behind in its development. If, then, we are primarily concerned with furthering this development, the usefulness of the classification we adopt at any one level depends on whether such a classification will serve to link up our knowledge with knowledge on another level.

How does such a criterion apply to the classifications of factor analysis? The factors derived from factorial analyses, as Burt has insisted, are statistics in exactly the same sense as a standard deviation or a standard error. They cannot be reified, *a priori;* that is the factors cannot be taken to be anything more than principles of classification, cannot *a priori* be equated with physiological or psychological events, the effects of a certain hormone, for example, or a so-called property of the mind. But though factors cannot *a priori* be reified, they *may*, on occasions, represent the direct expression of a physiological or psychological event. Now it seems to me to follow from what we have said that a factor will only prove useful if in fact it *can* be reified. It is here that the physical anthropologist has a great advantage over the psychologist. He has a number of other facts about growth and physiology which can guide him in judging whether a given set of factors can reasonably be reified, and if so, what, physiologically speaking, they represent. The psychologist usually has to rely on his intuitions about the structure of the mind.

Our decision then as between oblique or orthogonal factors, Sheldon's components (better quantitated, perhaps, in the future) or Burt's factors lies in their correlations with other measurements at other levels, above or below their own, of personality. Judged thus, Sheldon's system has already proved its usefulness by its relations to temperament, if, indeed, future work on Sheldon's measures of temperament (and not somebody else's different ones) confirms the relationship. Burt's factors have not up till the present time been securely linked with

Fig. 1[1] shows three individuals fairly near the extremes. The man high in endomorphy and low in mesomorphy and ectomorphy is, speaking in caricature, spherical; a sort of globule with a round head, large fat abdomen which predominates over his thorax, and weak floppy, penguin-like arms and legs. The second is the physical training instructor caricature, with cubical massive head, muscular neck, broad and muscled chest, and thick strong muscular arms and legs. The third, again in caricature, disappears when you look at him sideways; he has a thin peaked face with a receding chin and a high forehead, a thin narrow chest and abdomen, and spindly arms and legs. Naturally, only a very small percentage of people look like this; the majority have a moderate amount of each component, and so have as their *somatotype*, as the set of 3 ratings is called, such numbers as 433, 344 or 352. The number of possible combinations of 7 things taken three at a time is 343, but the three components are not independent. They are negatively correlated, so that a high rating in one precludes to some extent high ratings in the others. Thus 771s and 555s do not exist, but 641s and 444s do. 76 somatotypes occurred in Sheldon's 4,000 pictures, and only 50 were at all common. *It must be clearly emphasized that the somatotype is not like the conception of the old fixed type, however; it merely results from making artificial discontinuities in a continuous scale.* The somatotype is a pigeon-hole into which is placed everybody who, on the continuous scales, is nearer that pigeon-hole than any other. In fact, most workers in this field now use halves on the rating scale, converting it to a thirteen-point scale, with a correspondingly larger number of smaller pigeon-holes.

One secondary point in Sheldon's classification must be mentioned here, because we will return to it at the end of this paper. It concerns the degree to which the male body resembles the female and vice versa. Sheldon calls this attribute the *gynandromorphic component*, and rates his subjects on this, again on a 7-point scale. The amount of femininity of build is not independent of the somatotype entirely, but different members of the same somatotype may nevertheless differ quite considerably in the gynandromorphic component. The man who is high in gynandromorphy has, amongst other features, large hips relative to his shoulders, a protuberance of fat above the symphysis, a fullness in the mammary area, and an approximation or overlap of the thighs when the heels are held together.

Having distinguished his somatotypes subjectively, Sheldon then put them on an anthropometric basis. The somatotype of a given individual may be found, without any element whatsoever of subjectivity, by another worker, who takes the standardized photographs, measures 17 diameters of the body from them, and consults Sheldon's tables. (At least this is theoretically so, but, so far, tables have only been published for the 16 to 20 age-group.) Thus any investigator who takes the trouble to measure his photographs may reach precisely those conclusions which Sheldon would have reached, and his results will be comparable with Sheldon's. However, the *original* scale still remains a subjectively determined one, set up by the operation of judgment of equal-appearing increments of somewhat complex stimuli. The root objection to Sheldon's system springs from this fact, that we do not know much about the nature of such scales. Consequently the further statistical manipulation of somatotype data is hazardous. A secondary, allied objection is that we are limited to making discrete jumps in our ratings across portions of the background scale: we cannot interpolate values from anthropometry with confidence, because of this uncertainty of the scale.

The factor analysis of physique, developed chiefly under the guidance of Sir Cyril Burt [5], meets both these objections. The technique is one of the forms of mathematical analysis designed to reduce to human comprehension large numbers of measurements taken simultaneously of several variables. In Burt's hands, this consists of reducing a matrix of covariances or correlation coefficients, such as may be obtained from a series of measurements on the body, to the result of the linear combination of a few other, mutually independent measures, called factors. Thus if we have three factors, A, B, and C, which together designate body build, we can describe a given individual not as measuring such and such in height, weight, leg length, head circumference, chest depth and so on, but more simply as so much of factor A plus so much of factor B plus so much of factor C. Put thus the method sounds similar to Sheldon's, and, indeed, so it is, in essence. The differences spring from the uncertainty of Sheldon's scale, and more importantly, as we shall see, from the fact that Sheldon's components are correlated, while Burt's factors are not.

We can tackle the first point by way of some of Burt's results. The analysis of his latest and most complete data [6] leads to a general factor, a main bipolar factor, and several other factors we shall discuss later. This first bipolar factor has been called the leptosome-pachysome factor by Burt, because its positive saturations are with girth and its negative with length, notably stature, leg length and arm length. Burt also worked out the multiple

[1] *Owing to the paper shortage it is not possible to publish the figures referred to in this paper. Copies of figs. 2 to 6 can, however, be obtained from the author.*

regression equation for this factor score, in terms of height, weight and leg length; measurements which, to within a small margin represented by a multiple correlation of 0·96, serve to estimate the factor. He was kind enough to let me have this equation in advance of publication, since I happened to possess these measurements on 50 students who had also been somatotyped anthroposcopically by Dr. C. W. Dupertuis, one of Sheldon's close associates, and myself in 1943. Fig. 2 shows the relation between estimated ectomorphy and Burt's leptosomic factor. It is quite obvious that Sheldon and Burt are measuring the same thing, perhaps in slightly different ways. Furthermore, allowing for some errors in the estimation of ectomorphy (since it was not done anthropometrically), for the fact that I had not taken leg measurements in precisely the same way as Burt's measurer, Dr. Morant, and for Burt's regression equation not being absolutely stable if other original measurements are taken, I suspect that the relationship is a straight linear one. The correlation coefficient is −·94. (There is a curious failure to assign any 3½ ratings and if some of the 4 and 4½ ratings were reduced, as this lack might reasonably indicate they should be, the correspondence to linearity would be still closer.) If this proves on further testing to be the case, then we can say that at least as far as ectomorphy is concerned, Sheldon's scale and Burt's are of a precisely similar nature [7], and that the analogue of the Weber effect did not occur, as Sheldon suggested it might have done, in his ratings [1, page 125]. (The other possibility is that the midrange ratings are somewhat inflated, as Sheldon suggests they may be.)

Now this makes it immediately impossible for any other of Burt's factors to correspond with mesomorphy or endomorphy, since the factors are independent and uncorrelated and the components are not. Could we then represent Sheldon's components by two further *oblique* factors; that is, factors which are themselves correlated? Such would seem to be a possibility, at least. But a further question, I think, must arise here, and that the simple one, why bother? Is there any advantage of oblique over orthogonal factors, or any disadvantage? This is ground fought over to exhaustion by the various schools of factorists; Thomson perspicaciously remarks that "it is really impossible to decide between them (the alternative procedures) without first deciding why we want to make factorial analyses at all" [8]. This I think we are in a better position to decide, with regard to physical measurements, than the psychologists are with regard to mental ones.

Factorial analysis, like any other statistical procedure, is a method for classifying things (or, speaking more strictly, events). Now classifications depend for their use on their *usefulness*, and the most desirable classification is that which, at the time of its use, sheds most light on the relations between one set of facts and another. We must then decide what sort of classification in the sphere of physique is most useful in illuminating studies of personality. We may interject here a way of considering personality. I wish to consider the word as referring to the sum total of all the attributes of a human organism, attributes which we describe at various *levels*. These levels on which we abstract and describe personality may be roughly defined following the traditional scientific divisions—anatomical, physiological and psychological, with the last divided into levels of temperament, character, disposition, cultural behaviour and so forth. A certain amount of knowledge has now accumulated on each of these levels, but the synthesis as between one level and another still lags behind in its development. If, then, we are primarily concerned with furthering this development, the usefulness of the classification we adopt at any one level depends on whether such a classification will serve to link up our knowledge with knowledge on another level.

How does such a criterion apply to the classifications of factor analysis? The factors derived from factorial analyses, as Burt has insisted, are statistics in exactly the same sense as a standard deviation or a standard error. They cannot be reified, *a priori;* that is the factors cannot be taken to be anything more than principles of classification, cannot *a priori* be equated with physiological or psychological events, the effects of a certain hormone, for example, or a so-called property of the mind. But though factors cannot *a priori* be reified, they *may*, on occasions, represent the direct expression of a physiological or psychological event. Now it seems to me to follow from what we have said that a factor will only prove useful if in fact it *can* be reified. It is here that the physical anthropologist has a great advantage over the psychologist. He has a number of other facts about growth and physiology which can guide him in judging whether a given set of factors can reasonably be reified, and if so, what, physiologically speaking, they represent. The psychologist usually has to rely on his intuitions about the structure of the mind.

Our decision then as between oblique or orthogonal factors, Sheldon's components (better quantitated, perhaps, in the future) or Burt's factors lies in their correlations with other measurements at other levels, above or below their own, of personality. Judged thus, Sheldon's system has already proved its usefulness by its relations to temperament, if, indeed, future work on Sheldon's measures of temperament (and not somebody else's different ones) confirms the relationship. Burt's factors have not up till the present time been securely linked with any physiological or psychological correlates. Later in this paper we shall, therefore, be concerned with establishing the relations of these factors to events during the growth of the child.

(2) Physiology, Growth and Physique

I have the feeling that clarification of the relations between physique and temperament will come about only by filling in the gap on the level between the anatomical and the psychological: that is, through the study of the physiological differences between people, a subject one might call *physiological anthropology*. The importance of such a study is really very obvious, yet curiously enough it has been much neglected. Partly the reason for this neglect has been, no doubt, the lack of a suitable classification of physique, in relation to which the physiological studies could be planned.

The first study of the physiological relations of the Sheldon components was reported in 1944 [9] when, in 50 healthy students, oral temperature and respiratory period at rest were found to correlate positively with ectomorphy and negatively with endomorphy. No correlation was apparent between the components and heart rate, cardiac output (ballistocardiograph method) and blood-pressure (except in so far as diastolic pressure was related to endomorphy because of the influence of arm width on both). It is of some interest that the two significant correlations of ectomorphy increased when the estimated leptosomic factor score was used instead of ectomorphy, and that this increase was somewhat more than that obtained by correcting the original correlations for broad categories. The leptosomic factor correlations were finally + 0·32 with respiratory rate and − 0·39 with oral temperature. A study of the partial correlations of oral temperature shows that when mesomorphy is held constant, the relation of leptosomic factor and temperature rises to − 0·52, and when the leptosomic factor is held constant, a relation of mesomorphy and temperature of + 0·43 appears. Both ectomorphy and mesomorphy independently make for a high oral temperature, the former more than the latter, at least in our sample. The mesomorphic ectomorphs have the highest temperatures, the ectomorphic mesomorphs the next highest. This is a rather crude observation but points the way, I think, to nicer studies of metabolic, endocrine and central nervous system differences. Older work has related various physiological variables to Kretschmer types or to indices such as the Pignet or simple Weight-divided-by-Height [10 to 16]. In the psycho-physiological field simple reaction time has been positively related to endomorphy and negatively to ectomorphy [17], and component dominance to certain ink-blot responses [41], and in the sphere of pathology some relations between disease and somatotypes [18], and neurosis and body build factors [19] have been reported. This study of physiological differences between adults is one uncharted approach to the subject.

A second approach seems equally promising; this is the study of human growth, or how the adult got to look that way. D'Arcy Thompson puts the relations of growth and physique most lucidly: "In short it is obvious that the *form* of an organism is determined by its rate of *growth* in various directions, hence rate of growth deserves to be studied as a necessary preliminary to the theoretical study of form, and organic form itself is found, mathematically speaking, to be a function of time" [20]. By reference to data already available on growth we can further clarify some of the relations of Sheldon's components and Burt's factors. The data we shall use are those of the Brush Foundation Study at Western Reserve [21] and of the Iowa Child Welfare Research Station [22].

The upper graph of fig. 3 shows growth in hip width of girls from birth to 17 years plotted simply as mean measurements of bitrochanteric diameter at each year of age. The lower graph shows exactly the same data as the upper, but plotted in a more informative manner. It is the *velocity* curve [23] of bitrochanteric diameter, showing how fast the tissues going to make hip width are growing. It is, in fact, the curve of the first derivative with regard to time of the upper curve. The points in the velocity curve are plotted as $\frac{\text{Bitroch.}t_2 - \text{Bitroch.}t_1}{t_2 - t_1}$. All the graphs to be presented are plotted in this form, $t_2 - t_1$ being one year. To bring the increments of different measurements to approximately the same scale, so as to be able to plot them on a single graph, every increment is divided by the adult mean value of the measurement in question. Thus the small increments of a small measurement are put on the same scale as the large increments of a larger measurement. The numerator is multiplied by 100 for convenience of scaling, making the final points to be given by $\frac{\text{Bitroch.}t_2 - \text{Bitroch.}t_1}{t_2 - t_1} \times \frac{100}{\text{Bitroch.}t_{17}}$, 17 years being taken as the adult value. The velocity of growth decreases from birth onwards, but at least two well-defined periods occur during which there is an upwards turn of the velocity curve, signifying an acceleration of growth. The larger of these two spurts is the better known, occurs in girls from about 9 years old to 13 and is called the *adolescent spurt*. The smaller of the two occurs from about 5½ to 7½ and may be called the *midgrowth spurt*.

I have taken the hip width as an example, because it takes part in *both* spurts, but the point is that by no means all measurements do so. Some diameters spurt at one time, some at another: the composition, we might say, of each spurt is different from that of the other. A person, then, who has a pronounced midgrowth spurt and a small adolescent spurt will end up different in form, supposing he started the same, from another individual who has a large adolescent but small midgrowth spurt. In precisely what ways he will be different we shall see presently: of course very great differences appear *before* the time of these spurts, which serve perhaps chiefly to put the finishing touches on to the physique. Fig. 4 shows the velocity curves of leg length and "trunk" length, or sitting height. From birth onwards the leg is growing in length faster than the trunk, until the time of the adolescent spurt. There is a marked difference between the two measurements at the adolescent spurt; leg length has a very small and minor spurt, while trunk length increases its velocity considerably. (The adolescent spurt in stature is, in fact, almost entirely due to growth of trunk; looked at from a biological point of view, stature is a queer compound measurement, of trunk and limb, and should be dropped.) Now it is here that we can, apparently, link up growth and Burt's body build factors. When the general factor of size, and the first bipolar, leptosomic, factor are accounted for, there remain at least four further well-defined group factors. One of these groups consists of the leg length measurements, as against a second which consists of trunk lengths. *It seems that these factors directly reflect relative growth rates as between leg and trunk occurring at the time of the adolescent spurt.*

This conclusion is supported, I think, by Mullen's most interesting study of the growth of factors from 7 to 17 [38]. Data for every other year of age were analysed separately by Holzinger's technique. Each age-group yields the same major factors; and there is also a further small group factor D_4 which represents trunk length. Now in the analysis of the 17-year-old girls D_4 is perfectly well marked, but as the ages get younger, so the identity of D_4 fades (that is its contribution to the total variance gets less and less), until at age 7 it is non-existent. It appears to emerge as separate from the limb and leptosome factors with the adolescent spurt, just when the growth curves diverge so radically.

We may become more ambitious, and look at the leptosomic factor itself. This is a very stable factor, in the sense that it has appeared in all Burt factor analyses in a very similar form [5, 6, 19, 24 and 28]. The chief negative saturations of this factor are with sitting height, leg length and arm length, and three of the chief positive saturations are with hip width, chest breadth and thigh circumference. We have growth data available for these six measurements, five of them being from the same subjects, with thigh girth from a different group. Fig. 5 shows the velocity curves; it is at once obvious that the lines in the upper half of the picture, which represent the length measurements, continue downwards from age 5½ to 7½, while the lines in the lower half, which represent breadths, turn upwards for a time. *That is, the length measurements do not take part in the midgrowth spurt, which is well marked for all the breadths.* We may surmise that the leptosomic factor refers at least in part to events of relative growth occurring at this time. These events, however, do not by any means account entirely for differences between individuals in ectomorphy or the leptosomic factor. Carter and Krause's analysis [37] of the Bakwin data [40] on new-born infants shows even at this age the presence of a well-marked bipolar leptosomic factor accounting for upwards of 10% of the variance, with similar saturations to those found in adults (with two interesting exceptions). Since growth is an exceedingly regular process [23], it seems reasonable to assume that those who are high in the leptosomic factor as infants are, by and large, high also as adults. Whatever the processes are, in fact, that control growth-to-the-ectomorphic-form, they are in operation already in fœtal life. There are times during post-natal growth when such processes are seen functioning most clearly—either because they exert larger effects at these times, or because they are less overlaid by other growth processes. Such a time in the genesis of ectomorphy seems to be the midgrowth period.

It does appear, then, that we can identify Burt's factors with events occurring *at certain times* during growth. The question raised earlier is answered—the factors *can* be reified, as physiological processes, and they should, accordingly, prove useful. The nature of the physiological processes the factors refer to is not yet clear. I am much more inclined to think factors reflect the *reactivity* of a set of tissues at a particular time—physiological fields, if you like—than the secretion of a particular hormone. The major control of these processes is, without any doubt, genetic; though how much environmental stresses at particular times can upset them is uncertain.

I have said nothing about the relations of Sheldon's components to growth, but what we have said of the leptosomic factor applies equally, of course, to ectomorphy. Endomorphy appears to be extremely similar to McCloy's factor I or fat factor [39], which has high saturations in subcutaneous tissue measurements, limb girths, and chest depth. (It looks as though the correspondence between McCloy's factor I and endomorphy is about the same as that of Burt's leptosomic factor and ectomorphy.) This factor is present in 9-day-old babies, and persists with varying importance throughout all the growth period. There is, particularly, one other of Sheldon's components whose relation to growth is, I feel, of great interest. This is the gynandromorphic component, or the component of femaleness of form in the male. Prior to the adolescent spurt, there is very little difference in growth pattern as between boys and girls. As is well known, the adolescent spurt of the girls occurs about two years before that of the boys, and is less pronounced in almost every measurement. The chief exception is pelvic width. Fig. 6 shows, above, the male and female spurts which characterize most measurements—here shoulder breadth is taken as a rather pronounced example—and, below, the exceptional hip width. The major relative growth velocity during the spurt is of the hips in girls, and of the shoulders in boys. What other sex differences of this sort occur during the spurt we do not know, but these relations of the shoulders and hips and the rest of the body, are the major attributes of Sheldon's feminine component. It seems sufficiently certain then that the gynandromorphic component arises at the adolescent spurt. An important piece of data from the Adolescent Growth Study of the University of California [29] carries us still further here. The time at which the adolescent spurt begins varies from person to person, and, as I have said already, girls spurt a couple of years earlier than boys. What Dr. Bayley found [29] was that the boys who had an early spurt had a spurt which resembled to some extent the spurt of girls. Conversely the late-spurting girls had spurts which resembled somewhat the usual spurt of boys. It seems—and there is other evidence in human growth to support the idea—that the way each tissue reacts to a hormonal stimulus common to all depends on its age. At any rate, what happens is that early-spurting boys come to have a higher degree of femininity than late-spurting ones. Now it seems probable that, given optimal environmental conditions, the time at which the spurt occurs is genetically determined; thus the phenomenon would be brought into relation with the familiar occurrence of intersexuality in lower animals. Further, if we assume that the relation Sheldon subjectively described between the feminine component of build and that of mind is correct, we can see the mechanism whereby some forms of homosexuality occur. That the relation postulated between femininity of physique and behaviour is indeed a close one has been shown by the work of the Grant Study of Harvard [30, 31, 32], and by the correlation found by Child and Sheldon between physique and Terman-Miles' masculinity-femininity score [33].

Thus a solution of some of the outstanding problems of physique and of personality does seem promised by the physiological approach. The difficulty lies entirely in obtaining access to normal people to study them. There is, as Sir Cyril Burt emphasized in a letter to *Nature* four years ago [34], the strongest need for the establishment in this country of a longitudinal, comprehensive and adequately-staffed study of the growth of healthy children.

Sir Cyril Burt: Dr. Tanner has rightly drawn attention to the valuable assistance that may be gained, not only by medicine generally, but by psychiatry in particular, from the application of factor-analysis to the study of its problems. It is commonly supposed that psychologists introduced factorial methods solely to study mental abilities; but in this country such methods were applied almost from the outset to the investigation of physical and temperamental data. It is a method that is always appropriate wherever the phenomena to be investigated depend on a large number of inter-related variables which cannot as yet be disentangled by observational or experimental devices. It thus seems peculiarly suited to the study of neurotic and psychotic disorders.

I should, however, like to emphasize its limitations. It is of value chiefly in preliminary inquiries for confirming or modifying hypotheses relating to classification; it cannot claim to be a substitute for experimental research or clinical observation.

I think, too, that Dr. Tanner has rightly indicated that the best starting-point is to be found in the examination of physical characteristics. He has, I imagine, chosen the topic of body-types because they are supposed to be associated with certain temperamental and psychopathological tendencies. In this field, the best-known work, but by no means the most scientific, is that of Kretschmer. The doctrine is as old as Hippocrates: but scientific interest in the subject began with British physicians about a century ago—Addison, Laycock, Hutchinson and others, who were all largely influenced by the early work of Hunter. Their writings prompted the investigations of the French school; and it was from these in turn that Kretschmer derived his views. But, as Professor Major Greenwood pointed out, the most careful Continental work has been that of the school of clinical anthropology established at Padua by Di Giovanni.

In this country the attempt to investigate the problem by factorial methods began with studies of physical and temperamental measurements among school children. But the most extensive data have been provided by material collected during the recent war. In the R.A.F., over 30,000 men have been measured; and, at almost every age and nationality, the same two prominent factors appear—first the general factor of size, and secondly the bipolar factor contrasting growth in the long bones with transverse or circumferential growth.

The first or general factor has been studied particularly in connexion with attempts to assess nutrition; but it is the second or bipolar factor that is of interest to the psychiatrist. This appears definitely to confirm the old notion of the *habitus phthisicus* as contrasted with the *habitus apoplecticus*; and it is of interest to note that the former has proved to be significantly correlated, not only with tendencies to tubercular disease, but also with gastric and duodenal ulcer; while the latter is significantly correlated, not only with arteriosclerosis, coronary occlusion and allied vascular disorders, but also with diseases of the gall-bladder. The association with contrasted temperamental tendencies has turned out to be less marked than earlier writers supposed: it is both positive and significant, but, so far as evidence goes at present, far too small to be of practical use for diagnostic purposes.

It is extremely valuable to have heard a discussion of Sheldon's methods from one who has had the advantage of studying those methods at first hand. The methods themselves seem to me to be excellent. But I feel very dubious about the hypothesis on which Sheldon's nomenclature is based—the embryological hypothesis embodied in the terms ectomorphic, mesomorphic, and endomorphic.

To discover what are the real causal factors at work, a mere statistical analysis alone cannot suffice. Factor-analysis has been applied to growth-rates among school children; and has fully confirmed the distinction between what Julian Huxley and his co-workers have called isometric and allometric growth. The fluctuations of physical growth can be admirably exhibited by fitting the measurements obtained from children at successive ages by means of a generalized logistic curve: the results strongly suggest that the body-types observable among adults are produced by characteristic differences in the growth-rates for different parts of the body.

There is, however, an urgent need to supplement the results of these preliminary statistical inquiries by investigations along other lines in order to determine what part is played by genetic, biochemical, endocrinological factors and the like, in determining both body-type and the temperamental and psychopathic tendencies that appear to be indirectly correlated with it. Meanwhile, the data which Dr. Tanner has described and analysed form a most valuable contribution to our knowledge.

Severe Infections of the Mandible

By D. GREER WALKER, M.B., M.Dent.Sc.

I SHALL confine my paper to the treatment of severe mandibular infections. In this review of over 150 cases I propose to discuss the relative merits of surgery and penicillin.

Vaughan Hudson (1946) stated: "Our method of treatment, however, in all cases of acute osteomyelitis was to institute penicillin and wait and observe the progress of the case. It soon became apparent that penicillin swept the organism from the blood-stream and reduced the acute lesion to a chronic lesion. The subsequent fate of the patient depended upon the management of this now chronic osteomyelitis." He makes a further interesting statement on local penicillin: "Local penicillin as an adjunct to systemic penicillin made no difference to the results. In fact the recurrence rate when penicillin was used in addition to systemic penicillin was statistically higher than in those who had systemic penicillin only." Butler (1946) made the following observation: "We no longer consider it necessary to interfere with the primary focus of infection unless there is a local collection of pus."

What is the role that penicillin is to play in severe mandibular infections? Are we to use it alone or in conjunction with surgery as described by Mowlem (1944). Speaking about radical surgery recently Henry (1946) has stated: "The advent of first the sulphonamides and then penicillin has changed our conception of the disease and given radical surgery a degree of safety that was not formerly contemplated." This is true and there is no doubt that surgery is essential in the treatment of chronic osteomyelitis, but I agree with Vaughan Hudson that the best method of treating acute cases is to institute systemic penicillin and wait and observe the progress. To discuss the treatment of these severe infections a clear idea of the various types is essential and I have adopted the following classification:

(1) *Acute infections.*—(*a*) Involving chiefly the soft tissues, e.g. submandibular abscess; (*b*) involving chiefly the bone, i.e. osteomyelitis; (*c*) occurring in children.

(2) *Chronic infections of the mandible.*—(*a*) Involving a local area, e.g. local necrosis; (*b*) involving a diffuse area, e.g. chronic osteomyelitis; (c) involving the condyloid and coronoid processes, and the temporomandibular joint.

(3) *Infections of cystic origin, e.g. solitary cyst of the ramus.*

(4) *Infections occurring in bone that is already affected by some pathological disease.*—(*a*) Where the pathological condition is limited to the mandible, e.g. sclerosed mandible; (*b*) where the pathological condition involves the other facial bones or the entire skeleton, e.g. Albers-Schönberg disease.

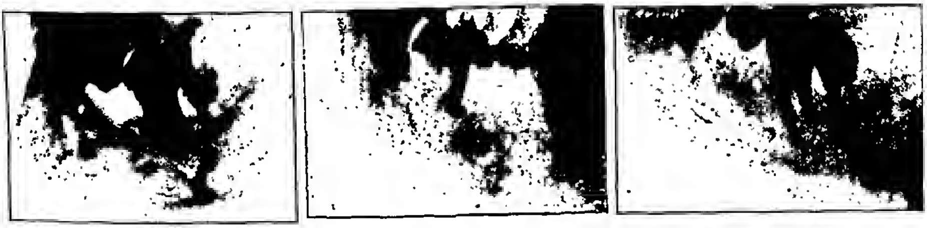
(5) *Specific infections, e.g. actinomycosis.*

(6) *Malignant disease, e.g. post-radium necrosis.*

(1*a*) *Acute infections of the soft tissues, e.g. submandibular abscess.*—The very rapidly spreading cellulitis of the neck scarcely comes within the framework of this paper. Fortunately much more common are the localized infections arising from some dental cause, or, perhaps less often, of traumatic origin following infection of a fracture. The removal of mandibular teeth will not drain or stem the advance of an acute infection which has passed from the immediate vicinity of the roots of the teeth. Frequently patients appear at hospital with the familiar dental abscess and offer the history that a tooth has been removed, teeth fractured in attempted removal, &c., and in spite of this treatment the abscess has continued to increase in size. The correct treatment of all these abscesses in the early stages has been the application of heat externally and intra-orally. When the presence of pus was established a submandibular incision was made with good dependent drainage. This treatment in the past has produced excellent results. Nowadays the use of penicillin instituted early in the treatment of these acute infections prevents many an acute abscess, or a severe bone infection. So often the infection has progressed for some days and is beyond hope of complete resolution. In such cases where penicillin is given the abscess may be incised and drained, or the pus evacuated and some penicillin placed in the abscess cavity without dependent drainage. At present I prefer to employ dependent drainage for a short time rather than a primary suture; the degree of recovery has been more rapid when penicillin has been given and the old principles of surgery employed. Following the control of the acute infection the cause must be removed. I, like many others, advocate this after the acute infection has subsided. Before passing to the bony infections we ought to consider the dental abscess in which the cause is not always apparent at the time. I have seen on occasions what appears to be a subperiosteal abscess and on careful examination no cause can be found. Whatever the ætiology the abscess must be treated as already outlined and if no cause is found on further thorough examination the case should be observed at periodic intervals. Sooner or later the cause will come to light and can be removed.

(1*b*) *Acute infections of bone, acute osteomyelitis.*—It is rather surprising that infection giving rise to alveolar abscesses does not more often invade the bone to a greater degree. The infection seems to pass rapidly out of the bone into the soft tissues. This is very fortunate as the more widespread infection of bone causes greater difficulties in treatment. Acute infection of the bone has been labelled for many years "acute osteomyelitis"; let us not linger to discuss terminology but rather the treatment at present employed. The first method, introduced by *Mowlem* [3], a radical removal of bone coupled with the administration of penicillin, has proved effective. The second, the use of penicillin systemically without surgical interference will be the method of choice in the future. If the organisms are sensitive to penicillin I fail to see the need of surgery apart from the possible treatment of a residual infection. The first case that I treated without surgery was in 1944 when a patient was admitted to Stoke Mandeville Hospital with an acute infection of the mandible extending from one molar region to the other on the opposite side. This had resulted from the extraction of a premolar tooth. All the clinical signs of an acute osteomyelitis were present and radiological signs were just becoming evident. I discussed the case with Professor McIntosh and we decided to try the effect of sulphathiazole immediately. The following course was given:

(i) 2 grammes stat followed by 1·5 grammes four-hourly for three days; (ii) 1 gramme four-hourly for two days; (iii) 1 gramme six-hourly for two days. The total dose of sulphathiazole was 46·5 grammes over a period of seven days. All pain ceased after two days and all signs of clinical infection vanished within the week. The only signs of infection lay in the subsequent radiographs which showed the typical decalcification (fig. 1). The complete recovery of this case without surgery led us to adopt the same lines of treatment with the introduction of penicillin. The same result is true of cases treated by penicillin. The time factor is most important if complete resolution is to be obtained without recourse to surgery. Cases not seen early will undoubtedly need treatment for some residual infection. Penicillin used in these cases will, however, limit considerably the extent of the infection. I find it rather early to be dogmatic but the results so far more than justify the omission of surgery in the early stages of acute mandibular infections.

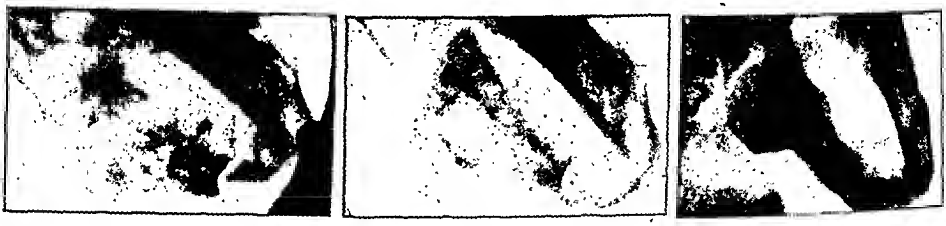


16.7.44. 16.8 44. 1.11.44.

FIG. 1.—*Acute osteomyelitis of the mandible.*—16.7.44: V. E., aged 31. Admitted to hospital. Early bone changes are just discernible on the radiographs. 18.7.44: Sulphathiazole course commenced. 24.7.44: Course completed; total dose 46·5 grammes. 16.8.44: Decalcification well marked on the radiographs. No clinical signs of infection remain. Discharged from hospital. 1.11.44: Out-patient radiographs show some decalcification still present along the lower border of the mandible. 23.11.46: No clinical or radiological signs of any residual infection.

(1*c*) *Acute infections occurring in children.*—The treatment of acute abscesses and acute bone infections occurring in children is similar to that already described for adults but there are two points that I should like to mention. The first concerns acute abscesses: There should be no hesitation in establishing early dependent drainage. If the infection is not controlled and is allowed to continue the inevitable result is a maldevelopment of the affected portion of the jaw. It is a pathetic deformity in an otherwise normal child. The second point relates to acute bone infections: The response of the young bone to infection is usually very good and the same holds true for the reaction of the teeth to such an infection. More than ever I feel that penicillin is indicated in these cases and surgery reserved for any residual infection. When it is necessary to perform a sequestrectomy great care should be taken so that the new bone is not removed nor the vital teeth disturbed or extracted. Failure to bear these points in mind will lead to gross deformities.

(2*a*) *Chronic infection of the mandible involving a local area.*—The commonest causes of local infection are a dead tooth or a retained root. This residual infection causes more frequently an intra-oral and less often an extra-oral sinus. There are other causes for which the teeth have been extracted and the socket has undergone varying degrees of necrosis. This may vary from the typical shedding of alveolar sequestra to the more extensive necrosis that may result in a pathological fracture (fig. 2). The removal of teeth has not prevented the infection from becoming chronic.



21.11.44. 5.12.44. 11.4.45.

FIG. 2.—*Pathological fracture of the mandible.*—21.11.44: M. E., aged 44. Admitted to hospital with multiple discharging sinuses in the lower right molar region and one external sinus below the lower border of the mandible. Radiographs showed a pathological fracture and multiple sequestra present. 28.11.44: Sequestrectomy performed intra-orally. 20,000 units of penicillin were given twenty-four hours prior to the operation and continued four-hourly. Local penicillin was applied on the intra-oral packing. 30.11.44: Packing changed and more local penicillin applied. Wound clean. 1.12.44: Systemic penicillin stopped. Local penicillin continued on daily changes of the packing. 15.12.44: Packing stopped, wound now well healed. 18.12.44: Discharged from hospital. 11.4.45: Seen as an out-patient; no signs of clinical infection present and radiological examination reveals good recalcification.

In treating these chronic infections the remaining portions of teeth and dead bone must be removed. There is little need to lay down hard and fast rules as to whether sequestrectomies should be performed intra-orally or extra-orally. It is obvious that it is preferable that the operation should be intra-oral but there are occasions when the method of choice must be external. Previous to the introduction of penicillin one saucerized the cavities in the bone following the removal of the dead bone. The cavities were packed for a short period. I think the same holds good to-day for operations inside the mouth when we use systemic penicillin. I have not observed any additional improvement in the cases where local penicillin has also been used. For external operations there is little need to pack the cavity when penicillin is given systemically. Where a good débridement has been performed suture of the wound is preferable to leaving it open.

(2*b*) *Chronic infections of the mandible involving a diffuse area.*—It is to be hoped that we shall no longer see the end-results of acute osteomyelitis with the multiple sequestra and areas of sclerosed bone. The following illustrates well a long-established infection of the mandible of some eighteen months' duration: Multiple sequestra were present causing several discharging external sinuses. Sequestra and teeth had been removed on a number of occasions with no improvement. The case was then diagnosed as actinomycosis following a positive report from the laboratory. When admitted to Stoke Mandeville Hospital we were unable to confirm the previous laboratory findings and it was felt that, apart from the multiple sinuses, the clinical picture did not resemble actinomycosis. In such cases extensive submandibular incisions are essential to open all areas of infection. In these cases I have given systemic penicillin, but it is doubtful of how much value this may be when the mandible is sclerosed. On account of this I have been rather reluctant to stitch the submandibular incisions immediately. I have felt the wiser course with our present knowledge is packing of the external wounds and by this method local penicillin can be applied. I am rather doubtful of the value of local penicillin in these cases. With less extensive infections and of a shorter duration it is preferable to close the external wounds on completing the operation.

The above case demonstrates very well the response on the part of the tissues to the invading infection. On rare occasions this reaction to infection seems to be completely absent. Fig. 3 is an example of the loss of almost the entire mandible. The radiograph shows the destruction of the bone. There seems to be no response on the part of the bone to deal with the infection. The history was most obscure but one could safely say that such a necrosis might well have been the result of phosphorus. With our present knowledge there is little that we can do when there is no response on the part of the bone. .

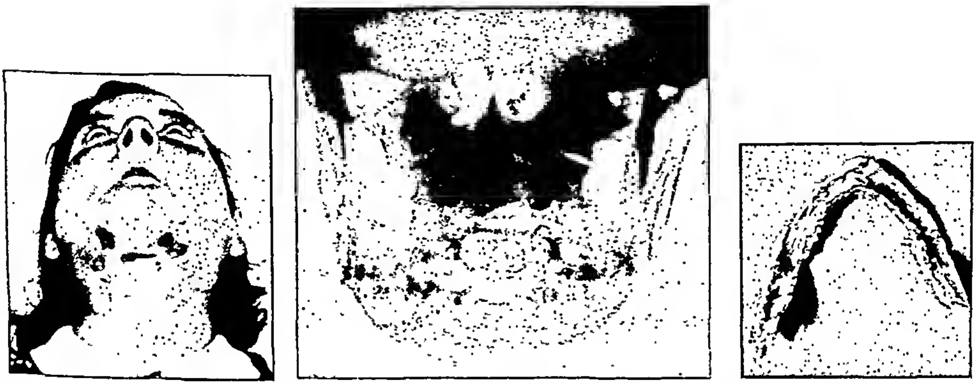


FIG. 3.—*Loss of almost the entire mandible.*—G. A., aged 41. Admitted to hospital with multiple submandibular and intra-oral sinuses. The radiograph shows the extensive involvement of bone. Shortly after admission practically the entire mandible was removed in one piece. It began to present through the alveolar mucosa as a sequestrum and was removed via the mouth.

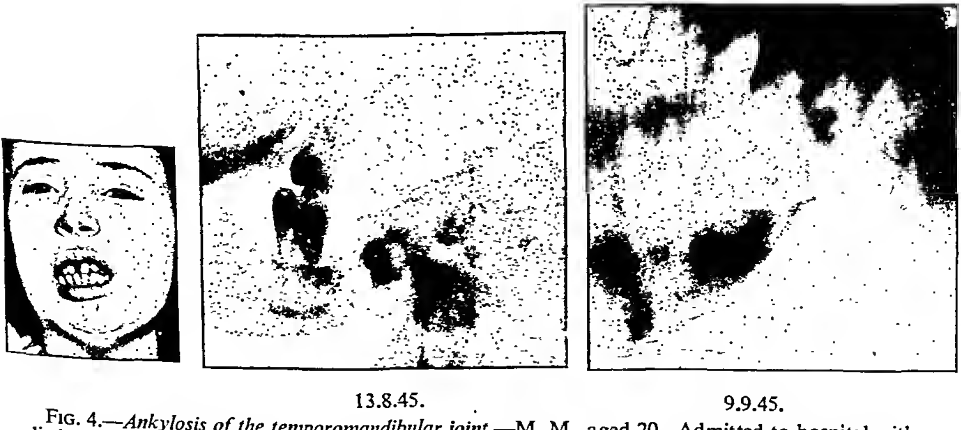
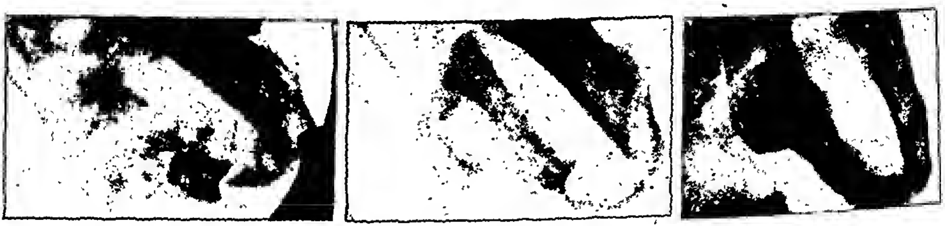
(2*c*) *Chronic infections involving the condyloid and coronoid processes and the temporomandibular joint.*—There seem to be two types of cases both of which eventually produce an ankylosis of the temporomandibular joint. The one is an ascending infection which starts in the region of the third molar and for some reason or other extends upwards to invade the joint. The other appears to originate from middle-ear infection and to spread towards the joint, condyle and coronoid process. Fig. 4



13.8.45. 9.9.45.

FIG. 4.—*Ankylosis of the temporomandibular joint.*—M. M., aged 20. Admitted to hospital with a discharging external sinus of some fifteen years' duration. The photograph shows the limitation of the temporomandibular joint, the first radiograph the infection around the molar teeth. Both teeth were removed via the mouth and in so doing the mandible was fractured. The tomograph shows the position of the fragments and a considerable loss of bone. This undoubtedly freed the mandible but the much sounder treatment would be the removal of bone higher in the ramus as was originally planned for the treatment of this case.

varying degrees of necrosis. This may vary from the typical shedding of alveolar sequestra to the more extensive necrosis that may result in a pathological fracture (fig. 2). The removal of teeth has not prevented the infection from becoming chronic.



21.11.44. 5.12.44. 11.4.45.

FIG. 2.—*Pathological fracture of the mandible.*—21.11.44: M. E., aged 44. Admitted to hospital with multiple discharging sinuses in the lower right molar region and one external sinus below the lower border of the mandible. Radiographs showed a pathological fracture and multiple sequestra present. 28.11.44: Sequestrectomy performed intra-orally. 20,000 units of penicillin were given twenty-four hours prior to the operation and continued four-hourly. Local penicillin was applied on the intra-oral packing. 30.11.44: Packing changed and more local penicillin applied. Wound clean. 1.12.44: Systemic penicillin stopped. Local penicillin continued on daily changes of the packing. 15.12.44: Packing stopped, wound now well healed. 18.12.44: Discharged from hospital. 11.4.45: Seen as an out-patient; no signs of clinical infection present and radiological examination reveals good recalcification.

In treating these chronic infections the remaining portions of teeth and dead bone must be removed. There is little need to lay down hard and fast rules as to whether sequestrectomies should be performed intra-orally or extra-orally. It is obvious that it is preferable that the operation should be intra-oral but there are occasions when the method of choice must be external. Previous to the introduction of penicillin one saucerized the cavities in the bone following the removal of the dead bone. The cavities were packed for a short period. I think the same holds good to-day for operations inside the mouth when we use systemic penicillin. I have not observed any additional improvement in the cases where local penicillin has also been used. For external operations there is little need to pack the cavity when penicillin is given systemically. Where a good débridement has been performed suture of the wound is preferable to leaving it open.

(2*b*) *Chronic infections of the mandible involving a diffuse area.*—It is to be hoped that we shall no longer see the end-results of acute osteomyelitis with the multiple sequestra and areas of sclerosed bone. The following illustrates well a long-established infection of the mandible of some eighteen months' duration: Multiple sequestra were present causing several discharging external sinuses. Sequestra and teeth had been removed on a number of occasions with no improvement. The case was then diagnosed as actinomycosis following a positive report from the laboratory. When admitted to Stoke Mandeville Hospital we were unable to confirm the previous laboratory findings and it was felt that, apart from the multiple sinuses, the clinical picture did not resemble actinomycosis. In such cases extensive submandibular incisions are essential to open all areas of infection. In these cases I have given systemic penicillin, but it is doubtful of how much value this may be when the mandible is sclerosed. On account of this I have been rather reluctant to stitch the submandibular incisions immediately. I have felt the wiser course with our present knowledge is packing of the external wounds and by this method local penicillin can be applied. I am rather doubtful of the value of local penicillin in these cases. With less extensive infections and of a shorter duration it is preferable to close the external wounds on completing the operation.

The above case demonstrates very well the response on the part of the tissues to the invading infection. On rare occasions this reaction to infection seems to be in such conditions a sequestration can be a very lengthy process. The radiographs show the progress of the infection and the remarkable growth of new bone. An interesting observation in this case was the remarkable effect of penicillin on the soft-tissue infections as opposed to intra-osseous infection. In the early stages of the acute bone infection penicillin had no effect, but later in the treatment the patient developed a severe submandibular infection which was rapidly controlled by penicillin. I think there is some justification in these cases for not performing any major surgical operations.

(5) *Specific infections, e.g. actinomycosis.*—Up to now I have considered what might be described as pyogenic infections in and around the mandible. Specific infections involving the mandible are rare; the commonest of this group is actinomycosis. MacGregor [6] has pointed out the advantages of penicillin in treating this infection and I feel that I can add little to what has already been said. The place of surgery in the treatment of these conditions is confined to incising abscesses or less often to a débridement when the mandible is actually involved. Fig. 6 demonstrates such a case treated by penicillin and surgery. There has been no recurrence of the infection.

The treatment of these cases cannot be dismissed without laying stress on the excellent results of X-ray therapy. Fig. 7 shows a case treated entirely by radiotherapy. It would appear that the method of choice at present is a combination of X-ray therapy and penicillin.

FIG. 7.

FIG. 6.—*Actinomycosis involving the mandible.*—There was a history that some lower incisors had been extracted and the abscess which had been present continued to increase in size. When admitted to hospital there were discharging submental sinuses and the clinical picture was very unlike a dental abscess. The radiographs showed considerable infection in the incisor region. 20,000 units of penicillin were given four-hourly and a débridement performed. Dr. J. Murray confirmed the diagnosis from tissue removed at this operation. The penicillin was continued for six days. In spite of the good result obtained we should now increase the dose of penicillin, give it three-hourly, and over a longer period.

FIG. 7.—*Actinomycosis involving the soft tissues.*—B. D., aged 59. Admitted to hospital with what appeared to be a dental abscess. The only history obtained was the loss of a crown from ⌈5 and soon after this the abscess appeared. The diagnosis of actinomycosis was confirmed by Dr. R. Robinson and the case transferred for X-ray therapy (Middlesex Hospital). The following course was given:—

Course completed over two areas in 16 treatments spread over eighteen days. Size of field 6×8 cm.; dist: 40 cm.; kV. 220; Ma. 10; ½ value layer 2·1 mm. of Cu. Filter, Thoræus. Dosage rate 45 r/minute.

(1) Lesion direct, 3,000 r.
(2) Lesion from above 200 r.
Total time 67′ 45″.

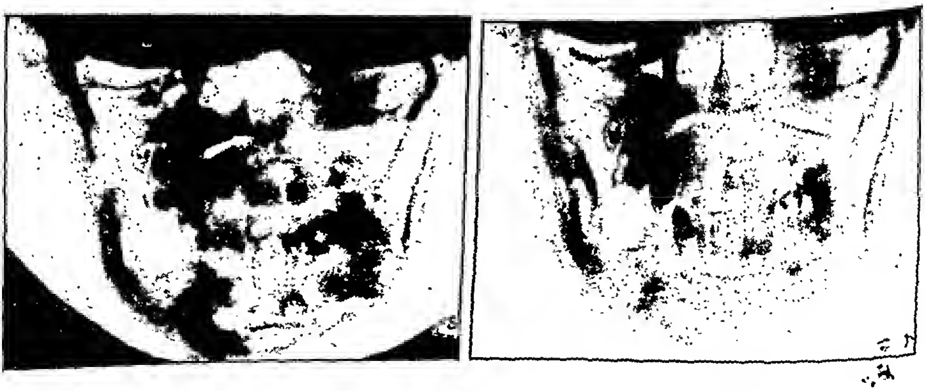
The second photograph shows the result two years later. No penicillin was given.

demonstrates the end-result of an acute abscess fifteen years ago. There is complete ankylosis of the temporomandibular joint. The external sinus is still discharging and no doubt caused by the infection around the molar teeth. The treatment in these cases is twofold. In the first instance any source of infection must be removed and when this has been dealt with, the ankylosis treated by extensive removal of the upper portion of the ramus together with its two processes.

(3) *Infections of cystic origin, e.g. solitary cyst of the ramus.*—The majority of cysts when they become infected cause little difficulty from the treatment point of view, but the solitary cyst involving the ramus, when infected, can be very troublesome. A marked degree of trismus in the acute stage of the infection prevents early operation and in such cases penicillin is more than helpful. The operation for these cysts lying high in the ramus is by no means a simple problem as I have stated in a previous paper [5]. There is a tendency for recurrence, particularly of the infection, if the orifice of the cyst is not kept patent with a skin graft.

(4*a*) *Infections occurring in bone that is already affected by some pathological disease—limited to the mandible.*—The type of case that I wish to describe here is by no means common. The mandible is for some reason of a sclerotic nature, a patient has a tooth removed and some infection follows. After the acute stage a very long process begins in which there seems to be a very low-grade infection present. The patient does not complain of any severe symptoms nor are they completely absent. The problem is whether to leave well alone or to interfere. What can penicillin do in these cases? It is doubtful if it is of much value. Is surgery worth while? The problem confronting us is the exact extent of the sclerosed bone and upon how much there is superimposed the new infection. As the boundaries are so ill-defined one hesitates to tackle the problem surgically. As these conditions occur in older patients the natural trend is to avoid surgery if possible.

(4*b*) *Infection occurring in bone that is already affected by some pathological disease—not limited to the mandible.*—These types of cases might be said to be even more rare than what we have just considered. To illustrate this group of cases I shall confine myself to one example, Albers-Schönberg disease, in which the problem of infection can be indeed very great. Fig. 5 demonstrates very well how



30.11.45. 11.9.46.

FIG. 5.—*Infection of the right mandible occurring in a case of "marble bones".*—Admitted to hospital with pain in the $\overline{8765}|$ region. The molars and premolar were extremely *tender and loose*, and had to be extracted. A lengthy process of infection then set in and the first radiograph shows the laying down of new bone, and the second—almost one year later—practically *complete separation* of the dead bone (*see Proc. R. Soc. Med.* (1938) 32, 282).

in such conditions a sequestration can be a very lengthy process. The radiographs show the progress of the infection and the remarkable growth of new bone. An interesting observation in this case was the remarkable effect of penicillin on the soft-tissue infections as opposed to intra-osseous infection. In the early stages of the acute bone infection penicillin had no effect, but later in the treatment the patient developed a severe submandibular infection which was rapidly controlled by penicillin. I think there is some justification in these cases for not performing any major surgical operations.

FIG. 3.

CASE I. [Figs. 1, 2, 3.]

There was also an area of bone destruction extending from the right lower canine to the left lower second premolar with a few sclerotic patches (fig. 2).

The enlarged right maxilla and malar bone gave a picture of diffuse and fine-grained hyperostosis. There was some exophthalmos of the right eye and a little ptosis on the same side (fig. 3a). Investigations showed blood cholesterol at the lower limit of normal and no diabetes insipidus, rendering a diagnosis of Schüller-Christian's disease unsuitable. Serum calcium lay within the upper limits of normal range; the blood-count was normal; there were no Bence-Jones proteoses in the urine; the Wassermann and Kahn reactions were negative; and radiographs of pelvis and long bones showed no abnormality. A biopsy from the right maxilla and the right side of the mandible showed the picture of osteitis fibrosa in each case. Dr. Laurent thought at one time that the case might be an early state of hyperparathyroidism; but the condition did not develop in that sense. When seen again in two years the bony protuberances had increased in size, especially that at the right mandibular angle, and the proptosis had increased (fig. 3b). The latter was apparently due to the formation of a boss of bone under the right eye. The serum calcium was then 10.9 mg. per 100 ml. It was decided to reduce the mandibular prominence for cosmetic reasons and this was done by Commander J. M. Banks and Mr. F. A. Walker (fig. 3c). The bone was found to be of leathery consistency. Professor W. D. Newcombe reported on the material removed as follows: "All the material is substantially the same, viz. osteitis fibrosa. The histology has changed considerably in the last two years, and now it is much more active with much woven bone formation and many spindle cells with very delicate collagen. If this type of alteration progresses much further the condition will become sarcomatous."

CASE II.—A married woman of 25 complained of swellings of the jaws. Abnormal thickness of the lower jaw on the right side was first noticed six years ago by a dental surgeon, and radiographs had since been taken and a diagnosis of adamantinoma made. There had never been any pain, redness, or discharge, and general health was excellent. Wassermann and Kahn reactions were negative. She had recently noticed new swellings on the left side of both jaws.

(6) *Malignant disease, i.e. post-radium necrosis.*—Radium necrosis is becoming very much less common with the advances in therapy. There is little that one can do in these cases in the way of any extensive treatment. The necrosis is slow and there is a reluctance to interfere. The deciding factor is the prognosis of the case. If this is poor then the best line of treatment is purely palliative, on the other hand with a younger patient with a good prognosis one might be tempted to greater efforts.

I think it is a little premature to lay down hard and fast rules regarding the optimum doses of penicillin, perhaps further work will strengthen our position.

My thanks are due to Professor Kilner, Messrs. R. P. Osborne and J. P. Reidy, and Mr. J. W. Hallam for permission to include some of their cases. My grateful thanks are due to Professor McIntosh and his staff and also to the radiologists to Stoke Mandeville and the Middlesex Hospitals, and to Professor Windeyer for his case treated by radiotherapy; I must also thank the Director-General of Medical Services of the Ministry of Pensions for permission to publish this Paper.

Regional Osteitis Fibrosa Affecting the Facial Bones: Two Cases

By Martin A. Rushton, M.D., L.D.S.

Many conditions differing in various ways have been grouped under the names osteitis fibrosa, osteodystrophia fibrosa, &c., on the grounds of their histological appearances.

A type quite commonly found in the jaws and in which there is no evidence of hyperparathyroidism has been called local or focal osteitis fibrosa, ossifying fibroma, and other names. This variety usually affects one bone only and often only one part of it. Occasionally cases occur in which there is the same type of lesion confined to the facial or cranial bones but affecting several of them. The lesion is, however, not symmetrical as it is in the classical descriptions of leontiasis ossea. Such cases may conveniently be called the regional type of osteitis fibrosa since there is in them no evidence of disturbance beyond the head region.

In the two cases to be described the lesions, chiefly of the hyperostotic-porotic variety, were first noticed towards the end of the second decade, were asymmetrical, progressive, and not associated with any observed blood changes, except a raised alkaline plasma phosphatase.

I report the first case by the kindness of my colleague, Mr. F. A. Walker.

Case I.—A soldier of 21 had noticed a lump on the right side of the lower jaw growing slowly for four or five years. There were no other symptoms. On examination it was found that the mandible was much enlarged in the region of the right angle and somewhat also around the symphysis. The right maxilla and malar bone were also much enlarged. Radiographs showed an area of bone rarefaction from the right lower first molar region to the condylar neck, with hyperostosis of a porotic kind (fig. 1).

Technique of Fenestration Operation.

Mr. E. R. Garnett Passe showed a coloured film of the fenestration operation performed through the endaural approach. In this operation a cartilage stopple was inserted. Illustrations were also shown of the new fenestra without the cartilage stopple insertion (*vide infra*). Mr. Passe said that he had used a cartilage stopple insertion in over 100 cases and that he had never obtained more than 40 to 45 decibel improvement; whereas in a further series of 70 cases, in which he has used his modified fenestra without the stopple insertion he has obtained as much as an initial 60 decibel improvement in two of his cases. He said that the cartilage stopple insertion was a technique he had learned from Dr. Lempert of New York, but he had given up the cartilage stopple insertion for the following reasons: (1) The cartilage stopple does not permit as great an increase in hearing acuity. (2) It does not materially reduce post-operative serous labyrinthitis. (3) It does not necessarily prevent bony or fibrous closure of the fenestra. (4) There is the further difficulty of insertion and the added risk that the membranous labyrinth might be injured during its insertion and associated manipulation.

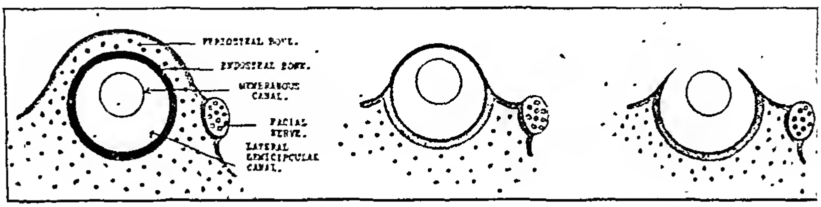

Fig. 1. Fig. 2. Fig. 3.

Fig. 1.—Cross section of lateral semicircular canal. Fig. 2.—Periosteal bone removed down to endosteal bone over a large area. Fig. 3.—Endosteal bone thinned down until the roof is finally removed.

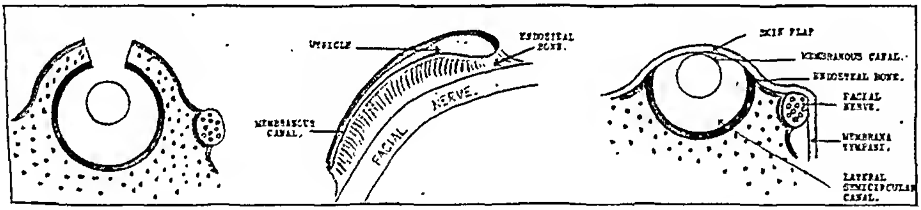

Fig. 4. Fig. 5. Fig. 6.

Fig. 4.—The old type of fenestra made for use with the cartilage stopple. Fig. 5.—Lateral view of the fenestra in roof of vestibule and canal showing fenestra seated on top of a ridge. Fig. 6.—Skin flap in situ. Note that it is in contact with the membranous canal.

However, he felt that the film would give a good idea of the technique performed in the fenestration operation. The film showed the various stages of the operation carried out under pentothal anæsthesia together with the first dressing, also under pentothal anæsthesia, six days later.

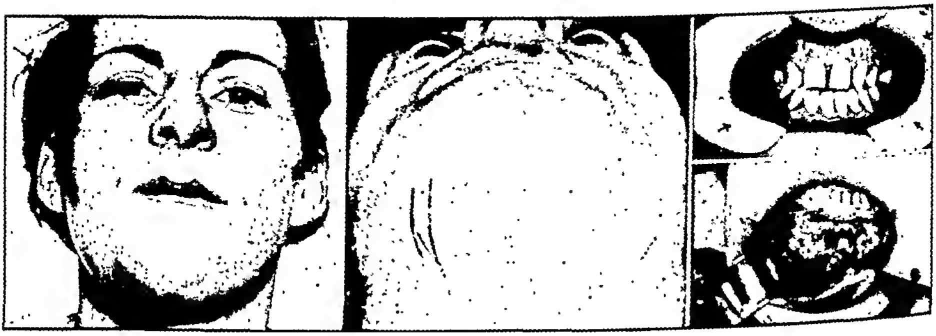
Bilateral Clinical Otosclerosis Treated By the Fenestration Operation Using the Cartilage Stopple and the Endaural Approach.—E. R. Garnett Passe, F.R.C.S.

History.—J. B. McG., aged 34. Increasing bilateral deafness and tinnitus. Deafness commenced at the age of 28 associated with high pitched severe tinnitus. Marked family history of deafness.

On examination.—Clinical and audiometric examination revealed him to be a case of clinical otosclerosis.

Operation (January 18, 1946).—Endaural incision, mastoid cavity excavated.

On examination the thickness of the lower jaw was found to be abnormally great especially at its anterior part on the right (fig. 4a). The alveolar process of the left maxilla was also very much thickened. There were visible veins running vertically in the skin beneath the chin (fig. 4b). The occlusion of the anterior teeth was abnormal and according to the patient was not formerly so (fig. 4c). Mucous membrane was normal. Radiographs showed that almost the whole mandible was affected by osteitis fibrosa of a hyperostotic-porotic type but with occasional patches of sclerosis (fig. 5). The texture of the bone was a very fine stippling, with occasional areas of almost complete bone absorption and with a thin but unbroken cortex. The alveolar and palatine parts of the left maxilla were affected in the same manner, the abnormal bone ceasing sharply at the mid-line (fig. 6).



(a) (b) (c)

FIG. 4.

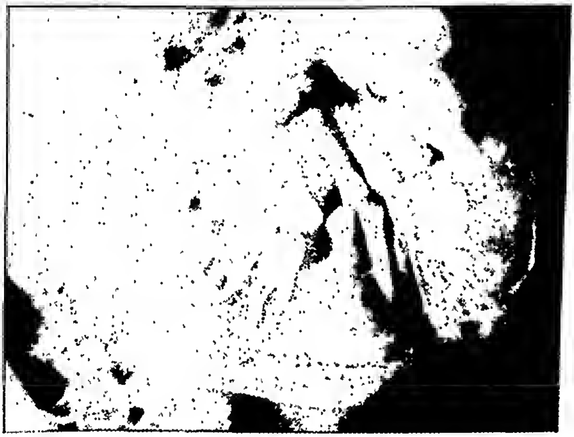


FIG. 5.

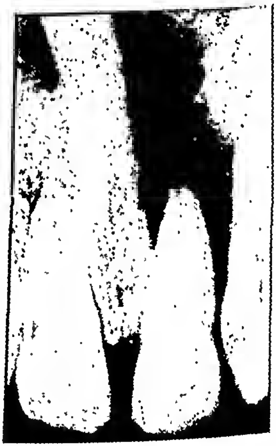

FIG. 6.

CASE II. [Figs. 4, 5, 6.]

The left malar bone seemed porotic compared with the right but was not clinically enlarged. There appeared also to be an area of porosis on the right side of the cranial vault, the size of two shillings, but again there was no clinical enlargement. Radiographs of the pelvis and right femur showed no abnormality; the serum calcium was 10·9 mg. per 100 ml.; and the plasma alkaline phosphatase was 45 phenol units.

On the advice of Dr. Levitt the patient was treated by radiotherapy preparatory to a cosmetic reduction of the bony prominences. The latter was performed five months later (Sir Harold Gillies and M. A. R.), a large section of the outer side of the lower jaw from molar region to molar region being removed and the prominence of the maxilla being sliced off. Sections of the tissue removed showed the same appearance in each jaw. All cortical bone was being actively absorbed, with large numbers of giant-cell osteoclasts, including the cortical bone around the mandibular canal, and the whole inner part of the bone had come to consist of a fine connective tissue containing innumerable small bone nodules of inactive appearance.. A certain amount of new subperiosteal and other bone was being formed. The lower left canine tooth, which had to be extracted, showed no abnormalities of structure and, in particular, normal cementum.

We found ourselves quite unable to offer any prognosis for these cases or to devise any useful treatment other than a palliative cosmetic procedure.

I am indebted to Sir Harold Gillies for allowing me to describe these cases from the Plastic and Jaw Unit E.M.S., Basingstoke.

Bilateral Clinical Otosclerosis Treated By the Fenestration Operation Using the Cartilage Stopple and the Endaural Approach.—E. R. Garnett Passe, F.R.C.S.

History.—J. B. McG., aged 34. Increasing bilateral deafness and tinnitus. Deafness commenced at the age of 28 associated with high pitched severe tinnitus. Marked family history of deafness.

On examination.—Clinical and audiometric examination revealed him to be a case of clinical otosclerosis.

Operation (January 18, 1946).—Endaural incision, mastoid cavity excavated.

Membrano-cutaneous flap fashioned, fenestration performed over vestibule and ampulla of lateral canal. Cartilage stopple fashioned from spine of the helix and inserted into fenestra. Jacobson's nerve on promontory destroyed by diathermy.

Cavity was completely healed within five weeks. Patient left hospital on twelfth day, and was able to play golf four weeks from the day of the operation.

Frequency (d.v.)	128	256	512	1024	2048	4096
Hearing before operation (decibels)	60	60	60	55	45	40
Hearing eleven months after operation (decibels)	35	30	30	35	25	15

His hearing has reached a satisfactory level of practical conversational value, and he now has no difficulty in hearing at his work as a draughtsman, or in his social life. To date there is no tinnitus in the operated ear.

An Operating Microscope for the Fenestration Operation.—J. F. SIMPSON, F.R.C.S.

Mr. Simpson said that he had brought this to the notice of the Section in order that members might have an opportunity of seeing an operating microscope which could actually be obtained in this country. It was made by Baker in Holborn. All that he had done was to have a prismatic attachment instead of a mirror or a direct light screwed on to the microscope itself. It had a useful magnification with the three sets of eyepieces—3, 7, and 10·5. The working distance was 130 mm.

Asked by Mr. Simson Hall what was the working distance at the highest magnification, he replied that it was very little different.

Review of Surgery of Otosclerosis

By TERENCE CAWTHORNE, F.R.C.S.

IT was in 1841 that Toynbee firmly established the connexion between deafness and ankylosis of the footplate of the stapes. In the previous century Morgagni, Meckel and Valsalva (quoted by Nager, *1928*) had all suspected that ankylosis of the stapes footplate might be responsible for certain forms of deafness, but it was Toynbee's work, which he continued to develop after his original publication, that really drew the attention of otologists to the condition that we know as otosclerosis, particularly when he stressed that, so far as his investigations took him, the organ of hearing itself was intact. It was this that made otologists realize that the one hope of a cure lay in overcoming the bony barrier that held back the sound waves from reaching the apparently normal cochlea. It is interesting to note that as recently as 1944, in a very fine paper on otosclerosis, Guild also remarked on the absence of any internal ear changes in a series of otosclerotic temporal bones.

In 1876, Kessel described a series of cases in which he removed the stapes. This procedure was tried by many and a Boston surgeon—Jack, 1894—described fifty such cases. There were, however, certain rather serious drawbacks to it; namely that the crura easily broke off leaving the footplate firmly fixed in the oval window and, where it was possible to remove the stapes, suppuration not infrequently supervened, giving rise at the best to a dead cochlea and, at the worst, to a dead patient.

In 1897 Passow, and in 1899 Floderus, described an operation in which they trephined an opening into the promontory, covering it with a mucoperiosteal flap. Like removal of the stapes, this operation soon fell into disrepute because it never resulted in lasting improvement and often made the patient worse. Thus it was clear to otologists at that time that the cochlear approach was not feasible and it was abandoned.

It was not until *1911* that *Bárány*, the Hungarian otologist, conceived the idea of decompressing the vestibular part of the labyrinth in the hope that, by reducing the perilymph pressure, more freedom of movement would be permitted to the already restricted stapes; he selected the posterior semicircular canal for this. In 1913, Jenkins, my predecessor at King's College Hospital, described before the International Medical Congress in London two cases in which he had made an opening in the external semicircular canal. At that time he thought that one of the contributing factors in otosclerosis might be an alteration in either the physical or chemical properties of the labyrinthine fluids, and he hoped that, by tapping the encased perilymph, the fluid might return to normal and some improvement in hearing might result. I was never fortunate enough to see him doing any of this work, but I understand from Mr. W. Wilson that any improvement so brought about was only fleeting.

During the early part of the first World War Bárány was serving with the Austrian Army and was captured by the Russians. As a Nobel Prize winner he was allowed, through the good offices of the International Red Cross, to go to a neutral country—Sweden—where he continued his work. There he attracted the attention of the Swedish otologist—Holmgren—who, in 1917, continuing on the same lines, and believing that decompression of the perilymph space was the answer to the problem, chose the superior semicircular canal, his object being to make an opening at its upper surface so that the dura might fall back on the top of the opening, thus delaying any bony closure. It is interesting to note that, within a matter of four or five years, three different otologists from three different countries each chose a different semicircular canal for his attack.

Holmgren soon abandoned the superior canal and turned his attention back to the lateral canal and even to the promontory, and, in 1921, he was trephining the promontory, fashioning the mucoperiosteal flap, using magnifying spectacles and a binocular dissecting microscope.

This work attracted the attention of a French otologist, Sourdille of Nantes, who visited Bárány and Holmgren in 1924 and was deeply impressed by the work they were doing. He decided that he must do this kind of work himself, but he soon started to think along somewhat different lines. He felt that the key to the problem lay in making and maintaining an opening into the perilymph space in such a manner that airborne sound waves could reach and be transmitted to the labyrinthine fluids. He felt that the best way of achieving this was to cover the fistula made in the lateral canal with a mucocutaneous flap continuous with the tympanic membrane. This, of course, meant an open operation and, in 1929, he described his operation of tympanopexy (Sourdille, 1932). It was an open operation done in two, three, or even four stages, these multiple stages being found necessary to avoid or combat infection. Although I have heard him describe his operation, I never had the opportunity of seeing him do it, but from the descriptions of the operation it was apparent that this was far from being a simple procedure.

During this time Holmgren, too, did some open operations, though on the whole he preferred the closed operation from behind the ear leaving the tympanum and attic intact; particular attention being devoted to preventing the fenestra from closing. In 1938, Mr. Macbeth and I had the privilege of spending several days with Holmgren and we were able to see him do several operations. He then was using radon emanations to discourage the regrowth of bone over the fistula.

In 1938 Lempert of New York described a one-stage open operation in which the approach was made through the meatus and which was similar in principle to that of Sourdille. It was done in one stage instead of in three, and the endaural approach seemed to cause less reaction and the incidence of infection and other complications was slight. In 1940 and 1941 he described further modifications of his endaural fenestration. He had at first continued rather on the same lines as Sourdille, removing the head of the malleus and leaving the incus intact, but later he removed the incus as well, and brought the fenestra farther forward until it was what he termed *fenestra nov-ovalis*, lying in the dome of the vestibule and including a part of the ampulla just above the oval window and separated from it by the facial canal. He brought this fenestra farther forward for two main reasons:—firstly because, as he said, new bone formation was rarely found in that part of the capsule of the labyrinth, and secondly, because the bringing forward of the fenestra enabled it to be covered by mucous-membrane-lined Shrapnell's membrane instead of by the mucoperiosteal-lined membrane of the posterior meatal wall which was necessary when the fenestra was more posteriorly placed. He felt that in this way there was less chance of the fenestra closing up with bone. About this time he also described the insertion of a little metal obturator in the hope of keeping the fenestra open.

In 1945 Lempert again published his results with what he termed a mobile cartilaginous stopple: a small piece of cartilage suitably shaped and taken from one of the auricular cartilages which was placed within the fenestra and was covered with the usual tympano-meatal flap. In this connexion you may be interested to know that when I was in America last summer Lempert was not using a stopple. He said that, though he had not been using it recently, it was quite possible that he might return to it later on. I found that several other workers had also abandoned the stopple.

Shambaugh of Chicago in 1942 published an article in the *Journal of the American Medical Association* in which he described the Lempert technique but adding to it constant irrigation and the use of a binocular dissecting microscope. In July 1946 in the *Archives of Otolaryngology* he described in detail certain variations, or perhaps I should say, additions to the Lempert procedure for which he claimed better results. The removal of much periosteal bone from the canal around the fistula, the avoidance of splintering of the endosteal bone, having the bridge of membrane between the drum and the fenestra as short and as mobile as possible, sponge dressings for the cavity, and special positioning of the head during the early post-operative period, were some of the details on which he placed emphasis.

In the evolution of this operation to its present stage there are three names which stand out—Holmgren, Sourdille and Lempert; Holmgren for his enthusiasm, and for his patience and perseverance, and, particularly, for the value of his example in interesting others in this work at a time when surgical treatment was in disfavour; Sourdille, who deserves great credit for designing an open operation that allowed airborne sound waves to be transmitted directly to the labyrinthine fluids; finally, Lempert, whose superb technique and endaural approach have simplified and perfected the open operation and have made it so safe that now this procedure can be carried out without any danger to life and with negligible risk of infection. His one-stage procedure is really a simplication of Sourdille's operation and the principle remains the same, namely, to quote Lempert's own words, "to mobilize the perilymph and endolymphatic fluids".

It is of interest to recall that, in this country, in addition to the work of Jenkins already mentioned, Kisch, before the First World War, operated on a series of cases of otosclerosis, trephining the promontory and covering the fistula with a periosteal flap. Hutchinson described his experiences with Sourdille's operation before this Section in 1936; Howarth in 1937 gave an account of his experience of the Holmgren type of operation; and in 1939 Passe described a series of cases in which he had carried out a fenestration operation; in 1944 Simson Hall, before this Section, gave an account of his experiences with the fenestration operation over a period of six years.

Towards the end of 1945, not being at all satisfied with my own results from fenestration, I decided to revert to the earlier procedure of removing the stapes; this was done in some twenty cases. Some of the difficulties that had formerly been noted were encountered; one of them being that the crura broke off with great ease, leaving the footplate fixed in the oval window. It was, however, quite easy to break through the footplate, but not always easy, even with ample magnification, to remove the pieces as the footplate usually fragmented inwards, the pieces adhering to the rim of the oval window. The results were variable, but on the whole disappointing, though I am not sure that this route may not in the end give good results. After seeing the work of Lempert, Shambaugh, Sullivan and Walsh and hearing of the experiences of other otologists during a visit to America in the summer of 1946, I decided to return to the fenestration operation. I have found that, no matter how carefully an operation is described nor how detailed are the illustrations of the various steps, it has been very easy for me at any rate to overlook certain minutiæ of technique that, in an operation such as fenestration, may count for so much.

This leads to the next part of this review, namely, the two factors essential for success in this operation. The first is complete familiarity with the procedure—familiarity not only from reading the descriptions but also familiarity from having done many operations on the temporal bone, on the cadaver and also of course of having seen an expert do the operation. My own experience has been that, although I was not unfamiliar with operations on the labyrinth, it was not until I had actually seen a number of fenestrations, through the kindness of my American and Canadian friends, that I was able to appreciate certain little technical manœuvres, particularly in connexion with the formation of the flap, which were very important and I realized that it was quite impossible for me to pick up everything from articles. In addition to work on the temporal bone and cadaver, and seeing other people perform the operation, it is important to gain familiarity in making the flap by using this approach for modified radical and certain radical mastoid operations. It is also advisable to take advantage of any case of labyrinthectomy for Ménière's disease to improve technique in making the fenestra.

There are two small details concerning the operation that deserve special mention: The first is magnification. In order properly to carry out this operation, and this applies particularly to the making and finishing off of the fenestra, it is necessary to work in a magnified field. Holmgren was the first to advocate the use of a binocular dissecting microscope giving ten diameters of magnification, but later contented himself with Zeiss-Ullstrom glasses giving two diameters of magnification. Lempert himself does not use a microscope for the operation and is able to do the most delicate work using only two diameter glasses. I do not however think that there are many people with eyes like his and most workers prefer a higher degree of magnification for the actual fenestration. I have been accustomed for some years to use a Leitz dissecting microscope giving ten diameters of magnification, and having a working distance of 22 cm. (Cawthorne, 1941) for all operations on the labyrinth and facial nerve, and I would not consider undertaking a fenestration without it.

The other detail that I think deserves special mention is the amount of time to be devoted to these operations. They should not be done as part of a routine list. Each takes from one and a half to three or more hours according to the difficulties of the operation and the experience of the surgeon, but the time factor should not be considered when embarking on them and I think that they should be done at a special session. Many surgeons prefer to do only one at a time, but it is possible for some surgeons to do two or even more in one session.

The next factor that requires consideration is the proper selection of cases. This is not an easy matter and each surgeon must, to a certain extent, form his own standards by which to select cases suitable for operation. An added difficulty in selection is that practically every patient who comes up for consideration is eager to have the operation. Most of them have heard of good results, or have read in the lay press glowing accounts of what can be expected. It is therefore of considerable importance at the very outset to be as objective as possible in the selection of cases and to be quite frank with those patients for whom an operation seems unsuitable. In their eagerness to have the operation some patients will even go to the extent of trying to deceive the examiner; sometimes they become very of the labyrinth, and secondly, because the bringing forward of the fenestra enabled it to be covered by mucous-membrane-lined Shrapnell's membrane instead of by the mucoperiosteal-lined membrane of the posterior meatal wall which was necessary when the fenestra was more posteriorly placed. He felt that in this way there was less chance of the fenestra closing up with bone. About this time he also described the insertion of a little metal obturator in the hope of keeping the fenestra open.

In 1945 Lempert again published his results with what he termed a mobile cartilaginous stopple: a small piece of cartilage suitably shaped and taken from one of the auricular cartilages which was placed within the fenestra and was covered with the usual tympano-meatal flap. In this connexion you may be interested to know that when I was in America last summer Lempert was not using a stopple. He said that, though he had not been using it recently, it was quite possible that he might return to it later on. I found that several other workers had also abandoned the stopple.

Shambaugh of Chicago in 1942 published an article in the *Journal of the American Medical Association* in which he described the Lempert technique but adding to it constant irrigation and the use of a binocular dissecting microscope. In July 1946 in the *Archives of Otolaryngology* he described in detail certain variations, or perhaps I should say, additions to the Lempert procedure for which he claimed better results. The removal of much periosteal bone from the canal around the fistula, the avoidance of splintering of the endosteal bone, having the bridge of membrane between the drum and the fenestra as short and as mobile as possible, sponge dressings for the cavity, and special positioning of the head during the early post-operative period, were some of the details on which he placed emphasis.

In the evolution of this operation to its present stage there are three names which stand out—Holmgren, Sourdille and Lempert; Holmgren for his enthusiasm, and for his patience and perseverance, and, particularly, for the value of his example in interesting others in this work at a time when surgical treatment was in disfavour; Sourdille, who deserves great credit for designing an open operation that allowed airborne sound waves to be transmitted directly to the labyrinthine fluids; finally, Lempert, whose superb technique and endaural approach have simplified and perfected the open operation and have made it so safe that now this procedure can be carried out without any danger to life and with negligible risk of infection. His one-stage procedure is really a simplication of Sourdille's operation and the principle remains the same, namely, to quote Lempert's own words, "to mobilize the perilymph and endolymphatic fluids".

It is of interest to recall that, in this country, in addition to the work of Jenkins already mentioned, Kisch, before the First World War, operated on a series of cases of otosclerosis, trephining the promontory and covering the fistula with a periosteal flap. Hutchinson described his experiences with Sourdille's operation before this Section in 1936; Howarth in 1937 gave an account of his experience of the Holmgren type of operation; and in 1939 Passe described a series of cases in which he had carried out a fenestration operation; in 1944 Simson Hall, before this Section, gave an account of his experiences with the fenestration operation over a period of six years.

Towards the end of 1945, not being at all satisfied with my own results from fenestration, I decided to revert to the earlier procedure of removing the stapes; this was done in some twenty cases. Some of the difficulties that had formerly been noted were encountered; one of them being that the crura broke off with great ease, leaving the footplate fixed in the oval window. It was, however, quite easy to break through the footplate, but not always easy, even with ample magnification, to remove the pieces as the footplate usually fragmented inwards, the pieces adhering to the rim of the oval window. The results were variable, but on the whole disappointing, though I am not sure that this route may not in the end give able to hear as well in a noise. This is perhaps the most significant and striking sign of all and I would say that the disappearance of paracusis is a definite contra-indication to operation.

(4) *Bone conduction.*—It is known that deafness due to internal ear changes is always accompanied by loss of acuity for bone-conducted sound and such loss has been generally accepted as evidence of perceptive (inner ear or nerve) deafness. There is, however, a group of cases in which loss of bone conduction is a prominent feature, but none of the other stigmata of perceptive deafness already mentioned are seen. It is therefore not beyond the bounds of possibility that shortened bone conduction can result from conditions other than perceptive deafness. It has been suggested that involvement of both round and oval windows by otosclerotic bone may produce this phenomenon and in favour of this is the fact that the rapidly advancing cases of otosclerosis which exhibit the flamingo-tinged drum often have loss of bone conduction without any other signs of perceptive deafness and it is in just these cases that the otosclerotic bone spreads widely and rapidly. Whilst very much shortened bone conduction usually means perceptive deafness, minor losses, particularly if they are unaccompanied by any other signs of perceptive deafness, may, in some instances, be due to other factors. With regard to the method of estimating the acuity of hearing for bone-conducted sound, this still presents certain difficulties. Bone-conduction receivers used in connexion with a pure tone audiometer do not give results that are in any way comparable as regards accuracy with air-conduction figures. For this reason it is, I feel, wiser not to put air and bone conduction results on the same chart because by doing so it may be inferred that they are of comparable accuracy. Many otologists still prefer to use the tuning fork and for those that do this it is wise to use the tuning forks of the three critical speech frequencies (512, 1024, 2048 d.v.). However, no matter how carefully they are carried out, bone-conduction tests are merely approximate and should not be regarded as anything else.

With regard to the quantitative aspect of deafness, it is necessary to have some idea of the amount of improvement that can be expected. It has been estimated that, in good cases, an improvement of 25 decibels can be expected for the critical speech frequencies. Bearing in mind that for these frequencies a hearing loss greater than 30 decibels reduces the hearing for speech to less than three feet it can be said that the best results as regards practical hearing for speech will follow where the pre-operative hearing loss for the critical speech frequencies has not fallen below 50 decibels. Of course whilst hearing for speech is the one thing above all that the deaf patient desires, an operation need not necessarily be ruled out because the hearing after operation is unlikely to reach the 30 decibel level. It is, however, important to give the patient some idea of how much improvement he can expect and the figures just mentioned form a useful guide.

A good functional result from fenestration can only be assured by careful judgment in the selection of the case and scrupulous attention to an admittedly difficult technique. If both these essential requirements are satisfied then it is reasonable to anticipate an improvement in hearing in about 75% of the cases operated upon. Of these, however, one-third will either have such a small improvement that it is not of any practical value, or the hearing will within a few months of the operation return slowly or quickly to its former level. Hence it may be said that, given favourable conditions, there is a 50% chance of a substantial improvement being maintained for a number of years. Exactly how long an improvement can last is not known, but it is generally estimated that if the initial improvement is sustained for more than six months it may last for several years. Nevertheless, most observers are in favour of waiting for two years before declaring that an improvement is worthy of being put on record. Of the remain-expert at this as not infrequently they have been through one or more special otological examinations before they finally appear as candidates for operation. I saw Lempert examine a series of cases and I was very impressed with the careful way in which he carried out the routine speech and tuning-fork tests. I noted that in several cases he tested the accuracy of the patient's replies by surreptitiously damping a struck tuning fork before applying it to the patient's ears or skull. On questioning him about this procedure he said that all his patients had already undergone several otological examinations and they were all trying to persuade him to do the operation, even though not a few were unsuitable subjects.

With regard to the type of case which is suitable for operation, I think it may be safely said that any case of uncomplicated otosclerosis whose hearing loss is not greater than 55 decibels for the critical speech frequencies (512, 1024, 2048 d.v.) is suitable for operation. There are, of course, a variety of conditions and cases of otosclerosis complicated by other conditions which may be said to hover on the border-line of suitability. Experience has, however, shown that the cases already mentioned as being suitable are the ones most likely to give consistently good results. It is generally agreed that this operation should be limited to cases of otosclerosis with normal tympanic membranes. It has been tried on cases where the deafness is thought to be due to intratympanic adhesions binding down the membrane and ossicular chain but, if we accept the principle that improvement in hearing is caused by movements of an unimpeded tympanic membrane being transmitted through a flap over the fenestra which is continuous with the tympanic membrane, then, clearly, good results can only come if the tympanic membrane is free to move. Generally speaking the selection of cases for operation may be considered under the qualitative and quantitative aspects of the deafness.

As regards the qualitative aspect of the deafness, it is well known and generally accepted that if the operation is to be successful the organ of hearing itself must be able, without difficulty or discomfort, to appreciate the increased sounds that a fenestration will bring to it. No matter how perfect the fenestration operation is, nor how patent the fenestra is maintained, little or no benefit will accrue if the organ of hearing itself is unable properly to perceive the sounds that are brought to it. There are certain criteria with which we are all familiar and by which we can tell when a patient with otosclerosis also has internal ear changes. The most significant are alteration in the timbre of the voice, intolerance of amplification, the disappearance of paracusis, and loss of ability to perceive bone-conducted sounds.

(1) *Alteration in the timbre of the voice.*—Patients whose deafness is of the conductive type only have, of course, soft speaking voices. Any noticeable increase in the loudness of the voice, particularly if it does not appear to be very well regulated and has a somewhat hollow sound, suggests internal ear changes that are preventing the patient from hearing his own voice properly. This should always be regarded as a bad sign so far as operation is concerned.

(2) *Intolerance of amplification.*—The patient with severe conductive deafness, as in otosclerosis, is usually able to tolerate amplified speech and often hears particularly well on the telephone or with a hearing aid. Any noticeable internal ear changes will reduce this tolerance of amplification as in such cases the margin between hearing and discomfort is reduced. It is for this reason that any intolerance of amplification should be looked upon as being an unfavourable sign because even if the fenestration were successful the patient might find the impact of unimpeded sound upon his defective cochlea unbearable.

(3) *Disappearance of paracusis.*—Nearly every patient with otosclerosis is able to hear better in noisy surroundings and it will be found that, in the more advanced cases where there are obvious signs of internal ear changes, the patient is no longer

able to hear as well in a noise. This is perhaps the most significant and sinister sign of all and I would say that the disappearance of paracusis is a definite contra-indication to operation.

(4) *Bone conduction.*—It is known that deafness due to internal ear changes is always accompanied by loss of acuity for bone-conducted sound and such loss has been generally accepted as evidence of perceptive (inner ear or nerve) deafness. There is, however, a group of cases in which loss of bone conduction is a prominent feature, but none of the other stigmata of perceptive deafness already mentioned are seen. It is therefore not beyond the bounds of possibility that shortened bone conduction can result from conditions other than perceptive deafness. It has been suggested that involvement of both round and oval windows by otosclerotic bone may produce this phenomenon and in favour of this is the fact that the rapidly advancing cases of otosclerosis which exhibit the flamingo-tinged drum often have loss of bone conduction without any other signs of perceptive deafness and it is in just these cases that the otosclerotic bone spreads widely and rapidly. Whilst very much shortened bone conduction usually means perceptive deafness, minor losses, particularly if they are unaccompanied by any other signs of perceptive deafness, may, in some instances, be due to other factors. With regard to the method of estimating the acuity of hearing for bone-conducted sound, this still presents certain difficulties. Bone-conduction receivers used in connexion with a pure tone audiometer do not give results that are in any way comparable as regards accuracy with air-conduction figures. For this reason it is, I feel, wiser not to put air and bone conduction results on the same chart because by doing so it may be inferred that they are of comparable accuracy. Many otologists still prefer to use the tuning fork and for those that do this it is wise to use the tuning forks of the three critical speech frequencies (512, 1024, 2048 d.v.). However, no matter how carefully they are carried out, bone-conduction tests are merely approximate and should not be regarded as anything else.

With regard to the quantitative aspect of deafness, it is necessary to have some idea of the amount of improvement that can be expected. It has been estimated that, in good cases, an improvement of 25 decibels can be expected for the critical speech frequencies. Bearing in mind that for these frequencies a hearing loss greater than 30 decibels reduces the hearing for speech to less than three feet it can be said that the best results as regards practical hearing for speech will follow where the pre-operative hearing loss for the critical speech frequencies has not fallen below 50 decibels. Of course whilst hearing for speech is the one thing above all that the deaf patient desires, an operation need not necessarily be ruled out because the hearing after operation is unlikely to reach the 30 decibel level. It is, however, important to give the patient some idea of how much improvement he can expect and the figures just mentioned form a useful guide.

A good functional result from fenestration can only be assured by careful judgment in the selection of the case and scrupulous attention to an admittedly difficult technique. If both these essential requirements are satisfied then it is reasonable to anticipate an improvement in hearing in about 75% of the cases operated upon. Of these, however, one-third will either have such a small improvement that it is not of any practical value, or the hearing will within a few months of the operation return slowly or quickly to its former level. Hence it may be said that, given favourable conditions, there is a 50% chance of a substantial improvement being maintained for a matter of years. Exactly how long an improvement can last is not known, but it is generally estimated that if the initial improvement is sustained for more than six months it may last for several years. Nevertheless, most observers are in favour of waiting for two years before declaring that an improvement is worthy of being put on record. Of the remain-expert at this as not infrequently they have been through one or more special otological examinations before they finally appear as candidates for operation. I saw Lempert examine a series of cases and I was very impressed with the careful way in which he carried out the routine speech and tuning-fork tests. (3) *Disappearance of paracusis.*—Nearly every patient with otosclerosis is able to hear better in noisy surroundings and it will be found that, in the more advanced cases where there are obvious signs of internal ear changes, the patient is no longer

Mr. W. G. Scott-Brown reported a series of 24 recent cases in which a foreign body inlay was employed in an attempt to ensure that the new window remained patent. These prefabricated stopples are made from unplasticized methyl-methacrylate. They are prepared by turning them on a watchmaker's lathe with a tool which cuts them to the shape of a press-stud. They are made in three sizes, the smallest being 0·85 mm. in diameter, the next 0·95 mm. and the largest size 1·05 mm.

One of these inlays is gently pressed into the new window which has been prepared by the usual technique. The correct size can be felt to snap into position and can sometimes be heard to do so. It is fixed firmly into position, requiring quite an appreciable leverage to get it out again owing to the shape of the flange, but can be seen to move slightly up and down on touching it afterwards.

The usual technique is employed for cutting the tympano-meatal flap and turning it over the plastic inlay. Flavine and paraffin wool is used to pack on to the drum and flap and gives an easy and satisfactory springy pressure.

The cases were all operated on during the past year, and, though recent, demonstrate that a foreign body inlay can be safely used as there was no mortality, no infection around the inlay and no inlay has come out.

These early results show the hearing in only one case slightly worse than before operation, and all others improved, with several between 25 and 35 decibels gain in the conversational range.

(Three of the cases referred to in this series were shown.)

Mr. V. E. Negus said that he had been an onlooker in the evolution of the surgery of otosclerosis from its beginning. He had had the privilege of working with Mr. Jenkins and he had paid various visits to Professor Holmgren. He was in New York when the first presentation was given of Lempert's modification. He had nothing to add as to the technique of this operation but he wished to say that for many years he had had the pleasure of working with Mr. Cawthorne at King's College Hospital. He had seen his whole career from its beginning, and as he thought that it was always very important that there should be some concentration of work in one man's hands, he had devoted himself in other directions and had always handed over to Mr. Cawthorne in their partnership at King's College Hospital those cases which involved operations on the internal ear.

He thought that Mr. Cawthorne had given a masterly presentation of the subject that morning and in particular he commended his balanced judgment in the selection of cases. He had seen the care which he had taken for so many years in working through the different steps which he had described, from Ménière's disease to this operation, with eventual success. It might be taken as an example of the way to present a paper and also of the way to learn to treat patients. Mr. Cawthorne had added lustre to the Otological Department of King's College Hospital, which was founded by Urban Pritchard and carried on by Cheatle, Jenkins and Daggett.

Dr. I. Simson Hall said that he wished to touch upon several points which Mr. Cawthorne had raised. The microscope he considered to be essential to the highest quality of work. The optimum magnification was about 8, and the working distance should be at least sufficient to permit the end of the instrument used being passed underneath the objective without any danger of touching it, making a working distance of about 25 cm. in the average double nosepiece microscope desirable. An instrument with a single nosepiece gave closer working distance with equal facility, and it was becoming increasingly obvious that a microscope specially designed for this sort of work was necessary.

With regard to the stopple he said the decision regarding this means of keeping the fenestra open would have to be delayed because there was as yet no series of cases reported which had been done a sufficiently long time to warrant comparison with the older series done without a stopple. Up to six months ago in his hands the stopple appeared to be giving about 10% better results than a comparative series done without stopple; as, however, there were other factors to be considered such a figure could not be used as definite evidence.

In using a stopple Dr. Hall said that his method was to take the level of bone down until the canal was raised above the surface for, if possible, half its depth. The roof was then removed and the stopple therefore was raised some distance above the level of surrounding bone. It seems possible that good results might be obtained without the stopple by similar technique in which the overlying flap was placed in direct contact with the membranous labyrinth; it would thus be impossible for any growth or fibrosis to destroy the opening. He was experimenting with this particular method in suitable cases.

Dr. Hall agreed with Mr. Cawthorne in the importance of studying the patient's voice, and it was very frequently a useful factor in the selection of cases. This of course was also usually connected with the presence or absence of paracusis, and Dr. Hall said that the presence of paracusis was of importance, and if paracusis was found to have disappeared that fact also was of the greatest value as it was unlikely that fenestration would then be successful.

ing 25%, 20% will have little or no improvement, whilst in 5% the hearing in the operated ear may be made worse and, very occasionally, may disappear entirely. For this reason the worse hearing ear is usually to be preferred for operation.

With regard to the amount of improvement that can be expected: In good cases the average improvement for the critical speech frequencies is in the region of 25 decibels, but greater improvement, particularly for isolated frequencies in the lower tones, has been noted. It is interesting to find that much improvement in the frequencies above 2000 is not common. It is important that prospective patients should always realize that the amount of improvement is usually limited to the figures that have been quoted.

With regard to complications of the operation, fortunately the mortality is negligible and most of the fatalities reported have been due to cardiac failure. As this is an open operation there is bound to be a small proportion of cases in which infection occurs and for that reason most otologists try and guard against post-operative infection by giving systemic penicillin before and after the operation for a short while. Also, many use the sulphonamides or penicillin in the cavity afterwards. Vertigo is one of the inevitable sequelæ but this is rarely troublesome and it usually passes off slowly within three or four weeks. One other complication which must always be mentioned to a patient who is contemplating an operation is the possibility of facial palsy. The inferior lip of the fenestra is little more than one millimetre from the facial nerve in its horizontal portion and now and again some damage to the facial nerve is bound to occur. Fortunately, in the cases reported, the resulting paresis has only been temporary.

Most of the patients who are suitable for fenestration are able to hear extremely well with a hearing aid, in fact one of the main indications for operation in a case of otosclerosis is an ability to stand the fairly powerful amplification that a modern valve aid offers. Therefore, it is always advisable to make quite clear to the patient that a hearing aid will give results just as good as, if not better than, an operation.

Finally, I have no doubt that the fenestration operation, properly performed on a suitable case of otosclerosis, offers a very real chance of improvement in hearing. I think that those surgeons with the necessary experience and ability are justified in carrying out the fenestration operation, should the patient desire it, and after all the facts have been put before him.

THE ÆTIOLOGY OF CHRONIC RHEUMATISM

Dr. W. S. C. Copeman: *History.*—The word arthritis is of great antiquity; it was used by Galen and his successors as indicating any affection of the joints of the body, as opposed to those of the feet for which the term podagra was used. "De Arthritide" was the title of books by Guillaume de Baillou (1591), Sennert (1631) and Schneider (1664). Arthritis being a generic term naturally included gout, which was not finally differentiated from other forms of arthritis until Sydenham did so in 1676 although de Baillou had suggested previously the possibility of the existence of other causes of chronic joint pathology. Medical thought was dominated until the seventeenth century by the humoral theory of pathology and ætiology, consequently arthritis and rheumatism were explained in terms of this hypothesis until well on into the eighteenth century, and indeed its influence is even now not entirely defunct. To Galen and his successors for many centuries rheumatism (ῥευματισμός) meant an internal discharge of a thin catarrhal humour from the blood into the joint cavities (arthritis) or elsewhere. Thus in the spring and autumn catarrhs of the respiratory mucous membranes are common and are accompanied by an external discharge of mucus, whilst a similar seasonal variation is recognized in rheumatic and gouty attacks. As is well known the word gout derived from this conception of the peccant humour being distilled drop by drop (*gutta*—drop) into the affected joints. Frederick Hoffmann (1660-1742) changed this conception somewhat by stating that "rheumatic" pain of all sorts is but a manifestation of a humour which distends the smallest blood-vessels of the affected part, so causing pain. Later writers such as Cullen (1710-90) attribute the onset of rheumatism and arthritis to the effect of cold and damp generally on a debilitated body. Later the mechanical school of Sauvages (1706-63) tended to regard arthritis as being a secondary effect of atony and rigidity of the soft tissues—fibrous tissues and muscles—surrounding and moving the affected joints. Nothing more constructive emerged until Landré-Beauvais separated the syndrome now known as *rheumatoid arthritis* from gout in 1800 under the name "goutte asthénique primitive"—no doubt out of respect for the traditional superiority of gout in this field, since he expressed his belief that they had no real connexion. *Osteo-arthritis* was first described and recognized as being a disease distinct from gout by William Heberden in his "Commentaries on Disease" published in 1802, the year after his death. It was only finally differentiated from rheumatoid arthritis in 1907 (A. E. Garrod). *Non-articular rheumatism* under the name of "chronic rheumatism" was distinguished from rheumatic fever and gout by J. Haygarth in a paper on the "Discrimination of Chronic Rheumatism from Gout, Acute Rheumatism, Scrophula, Nodosity and other Painful Diseases of the Joints and Muscles" (1813).

Ætiology of rheumatoid arthritis.—The humoral view has already been indicated, and held the field in arthritis of all types until Haygarth in a paper read to some friends in Warrington in 1779 described that "disease of joints almost peculiar to woman, and generally beginning about the period when the menses naturally cease".

Chemotherapy was a valuable adjunct or safeguard in the treatment of fenestration cases, but being in charge of a teaching clinic Dr. Hall was averse to the use of penicillin and other drugs as a routine. It seemed to him to be a reversion to the days of the carbolic spray when antiseptics rather than asepsis were the means of ensuring safety for the patient, and he preferred to rely upon a careful operative aseptic technique for his routine cases and to keep chemotherapy in reserve against the time when unusual circumstances or possibly breakdown in the technique rendered it necessary. To show learners in otology that surgical technique could not be relied upon appeared to him to be retrograde.

In only one case had Dr. Hall found that loud sounds had produced giddiness, this had been in the case of a young man who worked in a shipyard as a boiler riveter, and he found that work inside the boilers had a most unpleasant effect on him, although he was quite comfortable in an outside job.

With regard to facial palsy, Dr. Hall believed that one cause of this was working close to the facial nerve, particularly with drills of the polishing type. These drills, by the production of heat, were apt to cause temporary damage to the facial nerve, and it seemed to him that in continuous irrigation there was a safety device which would enable work to be carried on close to the nerve without any fear of damage.

In conclusion Dr. Hall wished to congratulate Mr. Passe on his film, for, having some experience of photography in the fenestration operation, he was able to appreciate the skill and care which had gone to the making of the film.

Mr. J. P. Monkhouse said that he was interested in the subject of bone conduction. He had seen a case only the other day which was not more than 10 decibels down on any frequency by air conduction, and yet there was no hearing at all by bone conduction except for two middle frequencies.

Mr. C. Hamblen-Thomas asked whether Lempert had made any examinations with the microscope of the fenestra and its surroundings in cases which had failed. It would be very interesting to know from such an examination what had been the underlying trouble. Speculation was very often wrong. He had some difficulty in getting hold of the magnifying eyeglasses, but he had discovered that they were now made in this country.

The President, in closing the discussion, said that he himself had not yet attempted this operation. Sourdille in his early work had described one in two stages and it would now be interesting to hear if this gave better results when applied to the later method of advancing the opening into the vestibule.

With regard to the use of a burr, technical information could be obtained from dental colleagues. He had been informed by one that the diamond paste burr was remarkably easy to control, a small one was efficient at slow speeds and if soft tissues were accidentally encountered they were not picked up or entwined by it.

What eventually happened to the fenestra might have to be decided in the post-mortem room. Shambaugh[1] had already reported from the laboratory what changes took place in this fistula in the monkey and he suggests that, at the present time, post-operative labyrinthitis is a more important cause of failure in the fenestration operation than bone closure.

Mr. Cawthorne had raised the question of the practical use of the hearing aid. This instrument was not popular with the deafened but its choice was a serious one if the happy results after some of these operations were not more lasting.

Mr. Cawthorne (in reply) said that first of all he would like to thank his friend and colleague—Mr. Negus—very much indeed for what he had said. He (Mr. Cawthorne) had always been very conscious of his good fortune in being associated with King's College Hospital and would always be grateful to his teachers, who included Mr. Negus, for all they had done for him.

In reply to Dr. Simson Hall he felt, with regard to the microscope, that this was a matter of choice and each surgeon would no doubt have his own preference. He (Mr. Cawthorne) had found that it was not practicable to work at a greater magnification than ten diameters and he agreed with Dr. Simson Hall that an adequate working distance was essential. With regard to chemotherapy, he felt that, as this was an open operation, prophylactic chemotherapy was justifiable and advisable. He never used prophylactic chemotherapy in closed aseptic operations such as that which he employed for Ménière's disease.

He had used a diamond paste burr for the past eight years in operations on the labyrinth and he preferred it to any other because of its gentle bite and the absence of any tendency to slip.

THE ÆTIOLOGY OF CHRONIC RHEUMATISM

Dr. W. S. C. Copeman: *History.*—The word arthritis is of great antiquity; it was used by Galen and his successors as indicating any affection of the joints of the body, as opposed to those of the feet for which the term podagra was used. "De Arthritide" was the title of books by Guillaume de Baillou (1591), Sennert (1631) and Schneider (1664). Arthritis being a generic term naturally included gout, which was not finally differentiated from other forms of arthritis until Sydenham did so in 1676 although de Baillou had suggested previously the possibility of the existence of other causes of chronic joint pathology. Medical thought was dominated until the seventeenth century by the humoral theory of pathology and ætiology, consequently arthritis and rheumatism were explained in terms of this hypothesis until well on into the eighteenth century, and indeed its influence is even now not entirely defunct. To Galen and his successors for many centuries rheumatism (ῥευματισμός) meant an internal discharge of a thin catarrhal humour from the blood into the joint cavities (arthritis) or elsewhere. Thus in the spring and autumn catarrhs of the respiratory mucous membranes are common and are accompanied by an external discharge of mucus, whilst a similar seasonal variation is recognized in rheumatic and gouty attacks. As is well known the word gout derived from this conception of the peccant humour being distilled drop by drop (*gutta*—drop) into the affected joints. Frederick Hoffmann (1660-1742) changed this conception somewhat by stating that "rheumatic" pain of all sorts is but a manifestation of a humour which distends the smallest blood-vessels of the affected part, so causing pain. Later writers such as Cullen (1710-90) attribute the onset of rheumatism and arthritis to the effect of cold and damp generally on a debilitated body. Later the mechanical school of Sauvages (1706-63) tended to regard arthritis as being a secondary effect of atony and rigidity of the soft tissues—fibrous tissues and muscles—surrounding and moving the affected joints. Nothing more constructive emerged until Landré-Beauvais separated the syndrome now known as *rheumatoid arthritis* from gout in 1800 under the name "goutte asthénique primitive"—no doubt out of respect for the traditional superiority of gout in this field, since he expressed his belief that they had no real connexion. *Osteo-arthritis* was first described and recognized as being a disease distinct from gout by William Heberden in his "Commentaries on Disease" published in 1802, the year after his death. It was only finally differentiated from rheumatoid arthritis in 1907 (A. E. Garrod). *Non-articular rheumatism* under the name of "chronic rheumatism" was distinguished from rheumatic fever and gout by J. Haygarth in a paper on the "Discrimination of Chronic Rheumatism from Gout, Acute Rheumatism, Scrophula, Nodosity and other Painful Diseases of the Joints and Muscles" (1813).

Ætiology of rheumatoid arthritis.—The humoral view has already been indicated, and held the field in arthritis of all types until Haygarth in a paper read to some friends in Warrington in 1779 described that "disease of joints almost peculiar to woman, and generally beginning about the period when the menses naturally cease".

In 1805 he expanded this in a published tract calling it "nodosity of the joints" and quoting 34 cases all but one in women. This would seem to foreshadow the role subsequently assigned by some later observers to the endocrine system in rheumatoid arthritis. Fuller in his book on "Rheumatism, Rheumatic Gout and Sciatica" (1852) agreed that the real factor must be a general blood poison, to the formation of which cold, debility and other conditions might conduce. The chemical view in the middle of the nineteenth century which postulated an excess of uric acid in the blood and tissues (or lactic acid—Todd), was introduced by Haigh, and enjoyed brief popularity. The name rheumatoid arthritis was coined in 1859 by Sir A. B. Garrod, and it is perhaps of interest to quote his reasons for doing so. He states that the term rheumatic gout is given to a disease having a peculiar pathology in no way related to gout, and not necessarily to rheumatism—and which is sometimes termed chronic rheumatic arthritis. He then says ". . . although unwilling to add to the number of names, I cannot help expressing a desire that one might be found for this disease . . . perhaps *Rheumatoid Arthritis* would answer the object, by which term I should wish to imply an inflammatory affection of the joints not unlike rheumatism . . . but differing materially from it". He considered its causation to be "exposure to the influence of powerful depressing causes, either mental or physical, and sometimes possibly by subacute rheumatic fever". He showed that there is no excess of uric acid present in the blood.

During the last third of the century, before the rise of bacteriology, the influence of the C.N.S. was invoked by Charcot (1868) and later by Pierre-Marie largely as the result of its bilateral and symmetrical distribution and its selective action on the small muscles of the hands. He also first drew attention to its centripetal mode of progression. The neurotrophic hypothesis associated with the name of Weir Mitchell also lingered on until the end of the century as evidenced by J. K. Spender's opinion in 1897 that "Rheumatoid Arthropathy" would have been a better name for rheumatoid arthritis had Garrod only adopted it instead of the latter in 1859. He regarded the disease as a neurosis. The current view at this time as expressed in Allbutt's great "System of Medicine" (1896 edition) was that rheumatoid arthritis was primary or secondary. Primary types resulted from general weakness due to mental wear and tear and worry, too frequent child-bearing, unfavourable hygiene, &c., and it often appeared as a sequel of influenza (of which outbreaks were common at that time). It is stated that "the term primary rheumatoid arthritis is justified by the fact that a state of the system and of the general health has been brought about which is favourable to a degenerative process . . . in addition there is the grave poisoning of nerve centres, and the disturbed nutrition which is the result". The interesting observation is made that "rheumatoid disease is a near neighbour of tuberculosis; and when a proclivity to tuberculosis exists in a family we may expect that any rheumatic member of that family may become rheumatoid". Secondary rheumatoid arthritis is stated to be "a special form which occurs after rheumatic fever—a sequence which justifies the adjective rheumatoid".

In 1909 A. E. Garrod introduced the metabolic factor as being causative of certain forms of chronic arthritis other than gout, a hypothesis which was taken further by Pemberton in 1912 who found metabolic disturbances in the form of lowered sugar tolerance in 60% of his cases of rheumatoid arthritis.

The infective hypothesis was initiated by Benjamin Rush, an American physician, who in 1803 cured a case of rheumatoid arthritis (?) of the hip by the removal of an aching tooth. In 1896 Bannatyne, Wohlmann and Blaxall described 100 cases of rheumatoid arthritis from which they had isolated a small bacillus with polar staining which they believed to be causative. In 1904 Goldthwait of Boston split off infective arthritis in his classification as being distinct from rheumatoid arthritis, of which the cause was said to be "idiopathic".

Soon after Still's description of the juvenile form of rheumatoid arthritis in 1896, Bannatyne *et al.* stated their belief—which was that also of Still himself—that the glandular enlargement seen in this form of disease is important evidence of infection.

Infective arthritis.—The rise of bacteriology in the last quarter of the nineteenth century led to the recognition of a large group of specific infective arthritides including gonococcal, streptococcal and dysenteric. Tuberculous arthritis had been recognized and described before this period on clinical grounds notably by Richard Wiseman, surgeon-in-ordinary to King Charles II, who thought it could be cured by the royal touch in common with the more banal manifestations of scrofula. It will be remembered also that Percival Pott wrote on tuberculosis of the spine in 1779, giving rise to the name Pott's disease. In this connexion may be mentioned also the belief of Poncet (1849-1913) that a tuberculous focus in the body will, under certain circumstances, give rise to a polyarthritis which is indistinguishable from rheumatoid arthritis of other causation, and sometimes other forms of joint disease including hypertrophic pulmonary osteo-arthropathy.

References to the role of syphilis in causing arthritis manifestations are to be found very soon after its establishment in Europe. Villalobos (1473-1560) and Fallopius (1523-62) are quoted by Rolleston. J. Russell of Edinburgh referred in 1802 to syphilitic arthritis, whilst Clutton's famous description of arthritis of the knee-joints in 1886 showed that congenital syphilis could also be held responsible for certain types of arthritic manifestations.

William Hunter (1861-1937) was the first observer to point out the possible remote effects, including arthritis, of focal—especially oral—sepsis. This hypothesis was much popularized by the late Sir William Willcox but has been used perhaps to explain too much.

ÆTIOLOGY OF OSTEO-ARTHRITIS

Although osteo-arthritis is a very ancient disease it was not clinically differentiated from other forms of arthritis until Cruveilhier did so in his paper published in 1829 entitled "Usure des Cartilages articulaires". He attributed the cause to inflammation, an opinion which was shared by most subsequent writers including Adams (1857), until Goldthwait (1904) stated his view that it is a constitutional affection with local joint manifestations which may be polyarticular—a view which would nowadays perhaps be considered to be more applicable to rheumatoid arthritis. Stockman in 1920 summarized the current view in the words "The cause of chronic osteo-arthritis is not known. Its onset has been attributed to cold and damp, trauma, previous joint disease, heredity and senile changes, but these can at most only be regarded as causes predisposing to the very definite and specific alterations which take place in the joints". I doubt if my colleagues will be able to advance very much upon this dictum of twenty-seven years ago!

In 1933 Lawford Knaggs working on Strangeway's specimens in the Royal College of Surgeons concluded that rheumatoid and osteo-arthritis merge clinically and pathologically and are expressions—at opposite ends of the same scale—of a single disease, which is toxic in origin.

Non-articular rheumatism.—Balfour writing in 1816 quotes Cullen's (1710-90) views on the ætiology of chronic rheumatism, in which category no doubt the non-articular forms are included. Cullen gives it as his opinion that it originates from a morbid affection producing congestion of the capillaries, tending to "an atony both of the blood-vessels and of the muscular fibres of the part affected, together with a degree of rigidity and contraction in the latter, such as frequently attends them in a state of atony". Balfour says: "Thus exposure to cold produces in one person catarrh, in another pneumonia, in another pleuritis, in another rheumatism, according to idiosyncrasy . . . moreover chronic is also often the consequence of acute rheumatism."

Little or no variation on this theme is found in other literature until we come to Stockman's view (1920) that fibrositis is the result of preceding general infections, or of local inflammations or injuries.

Dr. Philip Ellman: Our first step before we discuss the ætiology of chronic rheumatism is to attempt a definition and simple classification of chronic rheumatism although precision, in our present state of knowledge, is not possible. I cannot, unfortunately, include to-day a discussion of rheumatic fever, although I am personally of the opinion that the evidence continues to reinforce the unitary theory originally propounded by Jonathan Hutchinson and Poynton that the rheumatisms in the restricted sense in which we shall employ the term are allied to one another and constitute a family group among diseases due to some common weakness. Chronic rheumatism comprehends a group of diseases of the locomotor system characterized by pain and stiffness and, where joints are involved, by local swelling. General constitutional disturbance may or may not be present, depending on the nature of the lesion, and the onset, while usually insidious, may also be acute. The ensuing diseases of chronicity become, when untreated, associated with crippledom of varying degree. In view of their unknown ætiology a better designation is probably non-specific diseases of the joints and related structures.

Endless classifications—in the neighbourhood of sixty—have been introduced by numerous committees and have produced much confusion. My own preference is for a return, with slight modifications, to the classification originally propounded by Sir Archibald Garrod in 1890. He recognized two essential types of chronic non-specific arthritis, viz. rheumatoid arthritis and osteo-arthritis, more correctly described as degenerative arthrosis. If we include also non-articular rheumatism and bear in mind the less common chronic specific arthritides we have the basis upon which are built the simpler English and American classifications. The more specialized classification devised by a committee of the Royal College of Physicians in 1934 is the most comprehensive and scientific to date.

Analogy with tuberculosis.—The so-called chronic rheumatic diseases present a problem comparable in magnitude and significance to tuberculosis, with which they have much in common: they are responsible for much social and economic disturbance with infinite misery, disability and invalidism, more often than not occurring in the prime of life of the breadwinner of the family. But, while tuberculosis is an infectious disease of known ætiology associated with mortality, chronic rheumatism is, on the other hand, a disease of unknown ætiology associated with morbidity. It has hitherto been relegated to the list of uninteresting and incurable diseases and has been treated in the main almost with indifference by the profession, although few would contest that a life of helplessness, total incapacity with the patient a burden to himself, his family and society, is worse than death.

Nevertheless, the prevailing general attitude of defeatism in relation to the rheumatic diseases in general and to chronic arthritis in particular is quite unjustified. At present in-patient and out-patient facilities and provision for teaching and research are hopelessly inadequate. It is my firm conviction—and I may be pardoned for being somewhat provocative—that the rheumatic diseases are primarily the concern of the general physician, working closely with the general practitioner, rather than of the ultra-specialist, and they must resume their rightful place within the province of general medicine if they are to be successfully controlled. Only in this way will the patient be viewed as a whole, for these diseases are, like tuberculosis, systemic diseases producing local manifestations in the joints instead of the lungs, and both simulating, at one time or another, almost any other disease in general medicine.

Regarding the exact ætiology of chronic rheumatism we are regrettably in precisely the same position now as we were with tuberculosis in 1882 before Koch had discovered the tubercle bacillus. Many factors have been incriminated as ætiological and a vast amount of literature of a critical and non-critical nature continues to arise. While I propose to deal more particularly with environmental factors (occupational, physical and mental), for I believe with Ryle (1947) that the development of ætiological science must now be based more and more upon sociomedical investigation, I would like, however, to deal first with a few prevailing concepts.

First, *focal infection* with special reference to the rheumatoid type of arthritis: Of the last 100 cases attending the Rheumatism Unit at St. Stephen's Hospital, London County Council, the duration of whose disease varied from six months to twenty-five years and averaged 6·1 years, many were found to be divested of teeth and tonsils, some with sinuses drained, gall-bladder, appendix, and other organs removed. Yet in spite of such radical measures in dealing with supposed focal infection the patient was frequently no better but, on the contrary, despondent and lowered in morale. I calculated that no more than 3% of these 100 cases had genuinely benefited from such treatment, but in such cases of so-called secondary focal infective arthritis removal of a carefully assessed focus of sepsis may produce a dramatic response. Similar enthusiasm has even been extended to the osteoarthritic type of disease where, it would be generally agreed, focal infection can play no appreciable part. Non-articular rheumatism has likewise suffered similar insults in varying degree. There is surely need for a complete revaluation of the focal infection theory. I would urge the need for a more conservative and discriminating attitude in the final analysis. The work of Vaizey and Clark Kennedy, among many others, has supplied an admirable corrective in relation to chronic rheumatism and, having disposed of many of the prevailing ideas, they point out that the cure of according to idiosyncrasy . . . moreover chronic is also often the consequence of acute rheumatism."

Little or no variation on this theme is found in other literature until we come to Stockman's view (1920) that fibrositis is the result of preceding general infections, or of local inflammations or injuries.

Dr. Philip Ellman: Our first step before we discuss the ætiology of chronic rheumatism is to attempt a definition and simple classification of chronic rheumatism although precision, in our present state of knowledge, is not possible. I cannot, unfortunately, include to-day a discussion of rheumatic fever, although I am personally of the opinion that the evidence continues to reinforce the unitary theory originally propounded by Jonathan Hutchinson and Poynton that the rheumatisms in the restricted sense in which we shall employ the term are allied to one another and constitute a family group among diseases due to some common weakness. Chronic rheumatism comprehends a group of diseases of the locomotor system characterized by pain and stiffness and, where joints are involved, by local swelling. General constitutional disturbance may or may not be present, depending on the nature of the lesion, and the onset, while usually insidious, may also be acute. The ensuing diseases of chronicity become, when untreated, associated with crippledom of varying degree. In view of their unknown ætiology a better designation is probably non-specific diseases of the joints and related structures.

Endless classifications—in the neighbourhood of sixty—have been introduced by numerous committees and have produced much confusion. My own preference is for a return, with slight modifications, to the classification originally propounded by Sir Archibald Garrod in 1890. He recognized two essential types of chronic non-specific arthritis, viz. rheumatoid arthritis and osteo-arthritis, more correctly described as degenerative arthrosis. If we include also non-articular rheumatism and bear in mind the less common chronic specific arthritides we have the basis upon which are built the simpler English and American classifications. The more response to the same noxious agent may be manifested. Recently I have had in hospital several cases of rheumatoid arthritis complicated by rheumatic carditis with mitral stenosis. Taking 100 consecutive cases of the rheumatoid type of arthritis in my series I find that 8 of them had co-existent rheumatic carditis and I have notes of 22 further cases where rheumatic carditis (mainly with mitral stenotic lesions) has co-existed. This is in striking contrast to the extremely high incidence of rheumatic heart disease discovered by the autopsy studies of Young and Schwedel (1944), Bagenstross and Rosenberg (1941) and Bayles (1943) where the respective incidences were 65%, 56% and 22%. In Still's original cases of juvenile rheumatoid arthritis he reported several cases of pericardial adhesions. I have encountered at least one patient gravely ill with an acute fibrinous pericarditis who recovered, and Granirer (1946) reports a case of pericardial effusion with rheumatoid arthritis in which there was no history of rheumatic fever.

These and other studies suggest that in a large number of cases of slow progressive joint involvement cardiac lesions may be clinically silent, thereby escaping recognition. It has for some years been my practice to make a routine examination of the cardiovascular system in every case of rheumatoid arthritis and although my figures are only 8% (for clinical examination alone) I believe they are not insignificant in the light of existing literature. Should autopsy studies become more readily available, they may assist in establishing, as Young and Schwedel have already postulated, a "rheumatic state", probably highly dependent on age, with varying degrees of vulnerability of the heart and joints. I feel that the recently established Royal College of Physicians' Committee on acute rheumatism might well have had its terms of reference extended to include an investigation of its possible connexion with chronic rheumatism.

Systemic factors in rheumatoid arthritis.—In the rheumatoid type of arthritis, the systemic aspect of the disease is often of paramount importance. For example, in Felty's syndrome the accompanying lymphadenopathy, the leukopenia, splenomegaly, and sometimes hepatomegaly are interesting visceral accompaniments of the rheumatoid type of arthritis. The question arises whether these are manifestations of hypersensitivity. In this connexion I should like to refer to a case recently under my care, which I hope to publish in detail later, which proved to be one of Felty's syndrome. The case was characterized by a rheumatoid type of arthritis, splenomegaly, and hepatomegaly, lymphadenopathy and, later, a widespread purpura; at no time was there a leukopenia. The condition was complicated by a diffuse chronic pulmonary lesion, the radiological appearances of which were variously interpreted as compatible with Boeck's sarcoidosis, or with a pneumokoniosis (there was no history of an occupational hazard). Dr. Peter Kerley, who kindly saw the films with me, regarded the appearances as compatible with a periarteritis, an interesting suggestion in the light of a possible connexion between periarteritis and rheumatoid arthritis to which I will refer later. Autopsy findings confirmed the Felty's syndrome and, as far as the lungs were concerned, gave no evidence of sarcoidosis. They showed evidence of a curious chronic fibrosing bronchopneumonic lesion. Can this be interpreted as tissue hypersensitivity in the lung in keeping with hypersensitivity manifested elsewhere in the body? Dr. Robb-Smith, who kindly saw the sections for me, raised this as a possibility. I know of no comparable case in the literature.

In the light of such an interpretation of Felty's syndrome one is led to speculate on what is the essential difference, if any, in the pathogenesis of such conditions closely allied to rheumatoid arthritis as spondylitis ankylopoietica, psoriasis arthropathica, and Reiter's syndrome of non-specific arthritis, urethritis and conjunctivitis. The work of Rich and his co-workers has indicated an even wider association, on the basis of hypersensitivity between the rheumatoid type of arthritis and such rheumatoid arthritis following dental extraction is the exception rather than the rule and that bad teeth are not incompatible with good general health.

Time will not permit me to refer in detail to the extensive recent literature on ætiology in relation to *virus infection* and the theory of bacterial allergy with the interesting experimental work of Angevine, Rothbard and Cecil, Rich and his co-workers which merits attention. Schlesinger and his colleagues in 1935 mooted the possibility of a virus as the cause of rheumatic fever, a conception upheld by Eagles, Timbrell Fisher and others and extended also to rheumatoid arthritis. Sabin at the Rockefeller Institute has further confirmed this experimental work.

Basically, in the *bacterial allergy theory*, the acute and chronic rheumatisms are regarded as anaphylactic diseases with multiple lesions in the mesodermal system produced by continual antigen-antibody reactions in or on tissue cells. Visceral and other lesions may be explained as hypersensitivity manifestations in tissues elsewhere in the body. Levinthal believes that the debility of the antibody-producing system—the reticulo-endothelial system—is the basic cause of rheumatism and that all other indirect or precipitating factors interfere with the function of antibody production and with the capacity of reacting or maintaining the state of perfect immunity. The concept is attractive, appears rational and lends support to the unitary theory. It offers some co-ordination for the rheumatic group of diseases and suggests a relationship between the acute rheumatoid type of arthritis and rheumatic fever. It is possible, too, that the syndromes of a recurrent and transitory nature included under the term "palindromic rheumatism" of Hench and Rosenberg (1944) can be widened still further to include the so-called intermittent hydro-arthrosis, serum joint disease, allergic arthritis and allied syndromes as suggested by Parkes Weber, 1946. With regard to the so-called allergic arthritis it is not without interest to recall two long-standing cases of asthma who subsequently developed a typical rheumatoid type of arthritis with no recurrence of their asthma.

The following two cases of allergic arthritis and intermittent hydro-arthrosis which have recently come under my care are of interest in this connexion:

F. C. E., male, age 53. *Physical history.*—Perfectly healthy all his life until nine weeks ago when he received an injection of anti-catarrhal vaccine. Four days later there was an acute onset of knife-like pain in the left knee-joint, which became red, swollen, and tender, necessitating complete rest in bed for one week. During the next week he had acute and severe pains in the left ankle and both hips. These cleared with rest in a further fortnight. When he was seen, six weeks after the onset, the left knee-joint was still swollen and a large effusion was present. He had had 4 injections of the vaccine at weekly intervals and two days after each he had developed an urticarial rash. There was nothing noteworthy in the family or previous history. The blood uric acid was 5·6 mg. Uric acid in the joint fluid was 5·77 mg.%.

The presumptive diagnosis is that of gouty arthritis precipitated by an allergic response to foreign protein.

H. A. H., male, aged 41.—Thirteen years ago, following a minor injury, he had swelling of the left knee-joint which cleared spontaneously. Five years ago he fell on the right knee following which there was an effusion which did not clear for three months in spite of strict rest. Three years ago a recurrent swelling of the right knee followed a route march while on Home Guard exercises. Since that time there has been a persistent effusion of the right knee-joint of varying extent, increased by exercise and reduced slightly during periods of rest. On November 26, 1946, swelling and effusion occurred spontaneously in the left knee-joint as well and one week later he had bilateral hydro-arthrosis. Fourteen days later he complained of severe malaise and felt as if he were convalescent from a serious illness. On examination, in addition to swelling and recurrent effusion of the knee-joint there was pitting œdema of the left leg and ankle. He had no hæmorrhages or purpuric spots. There was no noteworthy previous or family history.

The heart and rheumatoid arthritis.—Rich and his associates have suggested that the basic characteristics of both rheumatic carditis and arthritis result from anaphylactic hypersensitivity and I have been struck, particularly during the war years, with the number of borderline cases lying between acute rheumatism and the rheumatoid type of arthritis. The inference to be drawn is that a variable tissue lationship to the circulating blood, the chemistry and cytology of various forms of arthritis, and, more generally, the metabolic activities of tissues taking part in the construction of joints, e.g. nutrition of the articular cartilage and respiration in articular cartilage: permeability of synovial membrane and articular cartilage are further problems awaiting the research worker. Each and all of these may contribute towards the ultimate goal of determining the exact ætiology of this group of diseases.

ENVIRONMENTAL FACTORS

The chronic rheumatic diseases have a long and extensive history. The skeletal remains of prehistoric man show that these diseases were among the hazards of the earliest human life—arthritis has, in fact, been discovered among the triassic dinosaurs. Studies of arthritis in wild animals show that rheumatism may develop not only when they are in captivity but also in their native habitat, occurring in both herbivorous and carnivorous animals.

Climate.—With regard to geographical distribution and climate it is generally accepted that chronic rheumatism is a disease of temperate climates and becomes diminishingly common as the equator is approached. On the other hand the interaction of dampness and rheumatism remains a controversial subject. Most probably damp has a deleterious effect on normal skin functions and may encourage catarrh and nasopharyngeal infections, thereby weakening resistance. In spite of this possibility, the general privation of trench life in Flanders from 1914-18 produced few cases of rheumatism among the troops. It is possible that damp surroundings may produce symptoms in a latent case of rheumatism, and although it is almost universally agreed that a damp house is detrimental to health it is not yet fully understood how it fosters the development of rheumatic disease. From a wide experience of the histories of rheumatic subjects I have known cases occurring in a damp house and becoming aggravated under such conditions but improving on removal to dryer surroundings. Damp, cold and other states of the atmosphere are believed to influence the development of rheumatic disease but Leonard Hill has often pointed out that dirt, artificially heated and ill-ventilated houses, overcrowding, &c., are more potent as causal factors than external weather conditions. Lack of a protective diet, as is seen in so many dietetic histories, may certainly be an accessory to the development of the disease although on the positive side there is no known specific diet.

Social history.—The art of taking a complete history is emphasized as one of fundamental importance in the course of medical teaching, but the extent to which such instruction is practised in later life is a matter for conjecture. One is, in fact, led to wonder how many of us make a really detailed investigation of the daily habits and environment of our patients. We should discover the previous, the family, the social and environmental histories (including physical, mental, occupational, hygienic, and dietetic factors), all of which may be ætiologically significant. As Professor Henry Cohen stated in a recent Skinner Lecture: "Such inquiries alone can unmask the evolution of disease and significance of the present state as revealed by examination. The eliciting of an accurate history reveals the quality of the practising physician. It demands care and courtesy, time and patience: the failure to take careful histories is in no small measure an expression of the economic structure of the present-day practice of medicine with its resultant hurry."

The interdependence of social, environmental and clinical studies and the contribution which a trained health visitor or social worker can make to a better evaluation of causal factors has for long been appreciated in the sphere of tuberculosis. Experience suggests the need for a comparable service in relation to the rheumatic diseases. Information so obtained makes it possible to assess the in-conditions as acute disseminated lupus erythematosus, periarteritis nodosa, dermatomyositis and scleroderma. Their work may ultimately lead to a better appreciation of these hitherto obscure conditions.

THE ENDOCRINAL FACTOR

The adrenals.—The experimental production by Selye and his co-workers of a polyarthritis, resembling histologically that seen in rheumatic fever and even in rheumatoid arthritis, following desoxycorticosterone acetate, demonstrates the role of the adrenal glands and has focused attention upon the endocrines. Urbach has even suggested that this may be an allergic reaction, i.e. the pathological lesions may be the clinical expression of an allergy to the adrenal cortex.

Thyroid.—As far as the thyroid is concerned the question arises whether the co-existence of hyperthyroidism in a rheumatoid subject is more than a coincidence. In the osteo-arthritic type of lesion the association of hypothyroidism is, in my experience, not uncommon. A syndrome of obesity, degenerative arthritis, and hypertension is frequently encountered in women at or about the menopause, such subjects also manifesting a raised blood cholesterol and a low basal metabolic rate. The response to thyroid medication is frequently dramatic.

The pituitary.—The part played by the pituitary and other endocrines is well seen in women. Rheumatic symptoms seem often to be exacerbated before the menses while during pregnancy there is frequently remission. I have no record of arthritis developing during pregnancy while Hench has described cases that have become pregnant as a therapeutic measure. The development of menopausal arthralgias with no joint changes is well recognized and usually responds to stilbœstrol. The rheumatoid type of arthritis may occur at this age-period although a degenerative type of joint disease, such as the syndrome already described, is more usual.

The potential significance of the pituitary in relation to chronic rheumatism has received considerable attention and has raised hopes concerning X-ray irradiation of the pituitary in the treatment of rheumatoid arthritis. Over-activity of the pituitary has been incriminated in certain cases of chronic arthritis of the osteo-arthritic type. In acromegaly an associated spondylitis is well known. In Cushing's disease joint lesions are known to occur. The relationship of acromegaly to pulmonary osteo-arthropathy has been noted by Fried in his work on lung cancer; he has made the interesting suggestion that the diffuse pulmonary osteo-arthropathy found in some cases is probably due to a dyspituitarism akin to acromegaly. In this connexion I would like to record the case of a man aged 55 referred to the Rheumatism Unit at St. Stephen's Hospital on account of pain, swelling and stiffness of both knees. Examination revealed a rheumatoid type of lesion with effusions into both knee-joints. The condition was complicated by a gross pulmonary osteo-arthropathy with an ossifying periostitis of the radius, ulna, femora, tibiæ and fibulæ. The patient also had a clubbed nose. Examination of the chest showed a right upper lobe bronchial carcinoma. Almost immediately following the removal of the growth by a lobectomy performed by Mr. Brock his knee-joint swellings began to subside, his fingers and nose became less clubbed, and now, after nearly two years, there is marked reduction of the subcutaneous tissue in the region of the terminal phalanages with practically normal fingers and toes. I have had two similar cases under my care.

Studies of joint anatomy, physiology, and pathology in relation to ætiology.—Such studies of the joint cavities and their related structures are frequently necessary with special reference to the synovial membrane and fluid and articular cartilage. Further investigations may include the origin of synovial fluid, its function, its re-

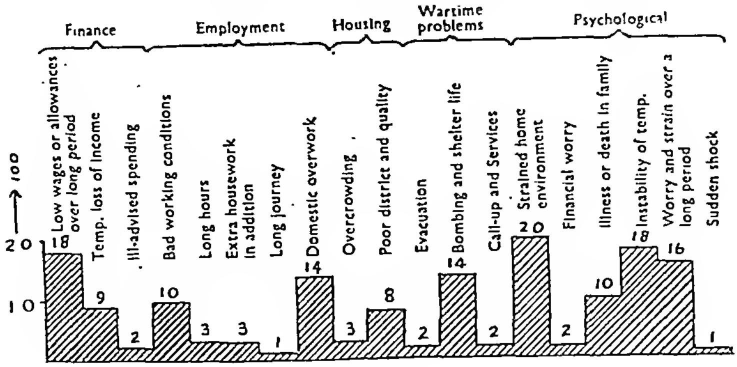

CHART III.

housewives (over 57%). Of 135 cases of rheumatoid arthritis under my care at the Leatherhead Emergency Hospital 62% (100 female cases) were housewives. Nevertheless, it is apparent that psychological problems are more outstanding than either employment or wartime problems. Physical trauma is, in my view, a major contributory ætiological factor in the osteo-arthritic type of disease and careful inquiry will often reveal such traumata in relation to occupation.

The age and sex incidence.—The following figures of 241 civilian cases admitted to the Leatherhead Emergency Hospital between September 1939 and September 1946 are of interest regarding the incidence of chronic rheumatism. The 178 female and 63 male cases can be classified as follows:

LEATHERHEAD EMERGENCY HOSPITAL

	Total no. of cases	Female	Male	Age range	Average age
Rheumatic fever	3	2	1		17
Chronic arthritis (rheumatoid type)	135	100	35	17–78 (f)	49
				15–74 (m)	45
Chronic arthritis (osteo-arthritic type) ..	65	53	12	32–89 (f)	60
				40–77 (m)	64
Non-articular rheumatism ..	34	22	12	15–81 (f)	46
				26–69 (m)	44
Gouty arthritis	4	1	3		59

ST. STEPHEN'S HOSPITAL (RHEUMATISM UNIT)

In-patients

Cases of Rheumatoid Type of Arthritis

	Total no. of cases	Age range	Average age
1945.. ..	45	21–72 (f)	47
		15–69 (m)	46
1946.. ..	50	22–65 (f)	48
		25–75 (m)	46

It will be seen that the average age range is fairly constant. The preponderance of women over men of all my in-patients and out-patients with a rheumatoid type of arthritis is roughly in the ratio of 3:1. L. S. P. Davidson in a series of 270 cases found 70% females and 30% males. Among osteo-arthritics my figures at the Leatherhead Emergency Hospital also show a preponderance of females but this may well be due to the particular circumstances prevalent during the war. My general experience does not show so high a disparity between the sexes. As far as age is concerned, generally speaking, cases of the rheumatoid type are seen fluence of social, domestic, physical, mental or industrial maladjustment in the origin and development of disease. It is not without interest to review the environmental factors obtained from social histories preceding the onset of disease in 100 cases of the rheumatoid type of arthritis between 1942 and 1944 (Chart I) and another 100 cases between 1944 and 1946 (Chart II) and also in relation to relapse of the disease in a third 100 cases (Chart III). The influence of finance, employment, housing, wartime problems, domestic, occupational, and psychogenic factors can be appreciated from these three charts. It will be noted that psychological factors are highest in both groups, that wartime problems are particularly marked on the second chart which covers the flying-bomb period when war strain was maximal. The effect of long hours is also marked in the 1944-46 group and from the occupational standpoint the incidence is seen to be extremely high among

1945	45	21–72 (f)	47
		15–69 (m)	46
1946	50	22–65 (f)	48
		25–75 (m)	46

It will be seen that the average age range is fairly constant. The preponderance of women over men of all my in-patients and out-patients with a rheumatoid type of arthritis is roughly in the ratio of 3:1. L. S. P. Davidson in a series of 270 cases found 70% females and 30% males. Among osteo-arthritics my figures at the Leatherhead Emergency Hospital also show a preponderance of females but this may well be due to the particular circumstances prevalent during the war. My general experience does not show so high a disparity between the sexes. As far as age is concerned, generally speaking, cases of the rheumatoid type are seen oftener at an age approaching 40 than at 20, and I have also had one female aged 78 and one male aged 74. I have noted that the more acute cases tend to occur in subjects of asthenic build, associated with marked wasting, the characteristic textbook description. The more insidious cases tend to occur in the higher age-groups; they may sometimes be quite robust, and I believe the 20 to 40 age-period of the textbooks requires a degree of modification. In my series only a few cases of the osteo-arthritic type have occurred before the age of 40; the age-period 40 to 60 and beyond of the textbooks is in keeping with clinical experience. The age-period in the non-articular group is very variable since this type may be primary, or secondary to another group.

Posture and body build.—Broadly speaking the tendency would seem to be for the younger rheumatoid subject (particularly where the onset is acute or subacute) to be of asthenic build while the older victim of degenerative joint disease is more often of robust hypersthenic build. Few patients have a perfect posture: of the thin narrow-chested individuals Osgood has said "their muscles are poor, their thoracic cages are narrowed, their diaphragmatic excursion is small, their abdominal viscera are sagged, the weight-bearing lines of their joints are not true, muscle tone is hard to maintain because the centre of gravity is disturbed". In the osteo-arthritic hypersthenic build postural disturbance with dorsal kyphosis and lumbar lordosis and abdominal sag are by no means uncommon. Obesity with its traumatizing factor contributes to postural disturbance and the mechanical strain on weight-bearing areas has a marked repercussion on the locomotor system. In every case the body posture, standing and on locomotion, should be noted as a routine measure.

Hereditary predisposition.—In a series of 100 cases of the rheumatoid type of arthritis I found that 20 had a significant family history. The ætiological significance of a genetically inherited predisposition is noteworthy (both mentally and physically). To cite two recent cases: two sisters suffering from a rheumatoid type of arthritis have the disease localized in the knee-joints while a third sister has died of rheumatic carditis. Another female patient, aged 50, with the rheumatoid type of arthritis, has been nursing a crippled sister with advanced rheumatoid arthritis for four and a half years, and a younger brother has rheumatoid arthritis. This constitutional susceptibility to disease is evident from the many reported instances of identical disease occurring in identical twins. Recognition of the underlying constitutional factors (inherent inferior joint tissues, impaired blood supply, body build, &c.) with the determining mechanism of varying susceptibility in the individual patient is secondary only in importance to external environmental factors.

Autonomic imbalance.—The conception of an autonomic nervous imbalance preceding by many years the onset of the disease is receiving growing recognition. Moreover, the psychogenic make-up of the patient may be intimately linked to the constitutional factor. Mitchell and I (1936), in studying a group of patients with chronic arthritis at the Order of St. John Clinic for Rheumatism, were impressed by the tendency towards morbid anxiety in many of the rheumatoid type, both prior to and following the onset of the disease. They were obviously more sensitive than usual to worry and emotional stress. An evaluation of the patient's psychogenic make-up in facilitating the onset of the disease, in impeding recovery, and in increasing the relapse incidence is important, although many observers have stated that subjects of degenerative joint disease are, on the whole, more placid and stable. This was contrary to our own experience, although genetic studies reinforced the view that the previous personality make-up largely predisposed the type of mental state following the illness. The relationship of mental states to physical dysfunction (i.e. the importance of endocrine autonomic dysfunction), and even to anaphylactic shock and the like have been described. It might be asked whether mental disturbance leads to organic disease in the arthritic subject. Our studies, as far as they went, did not permit a definite answer to this question. It seems likely, however, that both mental disturbance and organic disease are evidence of a general biological inadequacy.

Trauma.—With regard to degenerative joint disease a history of multiple minor or major physical traumata is often revealed, in contrast to the psychogenic traumata of the rheumatoid group but, as I have already stated, it is not the only precipitating factor. The inherent tendency to this form of arthritis is illustrated by the frequent incidence of the same condition in members of the same family. In such circumstances, with inferior cartilaginous and bone structure, the degenerative influence of trauma can be readily appreciated. Furthermore, disturbed body postures, obesity and occupational trauma, endocrine and metabolic factors may all aggravate the degenerative process. Senescence alone cannot be regarded as a causative agent having regard to those who, by reason, perhaps, of an inherited relative immunity, escape the disease.

Non-articular rheumatism.—Finally, I must refer to non-articular rheumatism, the so-called fibrositis. This condition has a symptom complex which includes pain, stiffness, and limitation of movement which can occur as a manifestation of psychoneurotic illness. The term was orginally introduced by Garrod in 1904 and has since been applied to so many maladies differing in ætiology and pathology but sharing a common symptomatology that some American workers have asked whether fibrositis does, in fact, exist as a clinical entity. Broadly speaking, however, a clinical definition of fibrositis would be an acute, subacute, or chronic non-suppurative condition characterized by pain and stiffness, especially on movement, affecting the fibrous origins, insertions, and aponeuroses of muscles, subcutaneous and deep fascia, ligaments, tendons, supporting tissues of certain nerves, and fibrous portions of joint capsules. The primary form of fibrositis is unaccompanied by any other recognized disease, while the secondary form it may also take may be an accompanying process in rheumatic fever, the rheumatoid and osteo-arthritic types of chronic arthritis, gout, certain pyrexial illnesses, &c. Since the ætiology is unknown such factors as occupation, climate, exposure to damp and cold, trauma and fatigue (mental or physical), diet, postural disturbance, metabolic, endocrine, microbic and focal infection may singly or jointly be significant. Time will only permit me to refer briefly to certain biographical studies which my colleagues and I have made during the war on civilian and military sufferers of so-called fibrositis at a Rheumatism Unit at St. Stephen's Hospital and at the Leatherhead Emergency Hospital, studies considerably extended since our original report published in 1942. I would like to preface these remarks by a few observations on Halliday's studies of insured persons who had been certified as unfit for work by reason of non-articular rheumatism. He emphasized that at least 40% were, in fact, incapacitated not by rheumatism but by psychoneurotic illness. Psychogenic muscular pain as an outward manifestation of acute or chronic emotional disturbance, causing autonomic disturbances and vascular instability with ischæmia or muscle spasm, is well recognized. We ourselves have been struck with the association of physical disablement and emotional psychoneurotic disturbances in cases of fleeting bodily pains which have not responded to several months of routine treatment. Of 50 cases labelled "fibrositis" all of whom had been ill for more than three months, we found (*Ann. rheum. Dis.* 1942) that 35 showed significant psychological disorders, 25 showing hysterical features, 7 suffering from anxiety states and 3 from depressive states. We noted a broad distinction between true and psychogenic fibrositis to the effect that in the organic form the pain was localized and could be reproduced by palpation, tension, contraction, or stretching in the affected area. The 35 psychogenic cases, on the other hand, complained of fleeting pains all over the body. In some cases of long-standing organic fibrositis the onset may well have been influenced by psychogenic factors which may also have exacerbated and prolonged the condition. It was, however, particularly noteworthy that psychological abnormalities were absent even in cases of long standing where the complaint could be sufficiently explained by gross structural lesions.

In psychogenic fibrositis the muscles serve as defence and attack in the struggle for existence and internal tension is most easily released by muscular action. Hence, if the external expression of aggressiveness in the form of muscular action is inhibited by repressing forces operative in the individual, muscular tension may result and is felt by the individual as pain and limitation of movement. This is commonly interpreted as fibrositis but I feel that the subject is at least comparable in importance to the so-called effort syndrome. This is now generally recognized as a psychoneurotic disability with a physical manifestation in the cardiovascular system, whereas the basis of certain so-called rheumatic pains is manifested physically in the locomotor system. Our work has received adequate confirmation by Flynd and Stuart Barber studying certain R.A.F. personnel.

It is often difficult to differentiate organic from psychogenic fibrositis but the following criteria, although not foolproof, are helpful:

(1) Pain and local tenderness.

(2) Reproduction of symptoms by pressure on tender focal points.

(3) Presence of nodules (which may be painful or painless). It should be noted that nodules are not infrequently felt in the course of routine examinations in subjects who are quite free from symptoms.

(4) The relief of symptoms on injections of novocain into trigger areas.

It must, however, be recognized that pain of a prolapsed disc, for example, or a spinal tumour with reflex lumbar spasm simulating lumbar fibrositis may be partially relieved by novocain infiltration.

SUMMARY

(1) The problem of the ætiology of the chronic rheumatic diseases with their wide systemic and local manifestations is essentially one for the general physician with a special interest in this sphere, and the general practitioner in consultation with a team of expert colleagues.

(2) The influence of various ætiological factors has been briefly assessed and reviewed.

(3) The development of ætiology in relation to environmental studies (biological, physical, occupational, and mental) and socio-medical investigations has been emphasized.

(4) A complete rheumatism service, visualized in the National Health Service, comprehends specialized rheumatism units, suitably placed according to the needs of the population, a plan analogous to the proposed tuberculosis and chest service. These units should, wherever possible, be centred in the atmosphere of a general teaching hospital with all its available ancillary services, linked also to an adequate number of beds in country hospitals run on sanatorium lines. In such institutions under- and post-graduate teaching, co-ordinated research as well as treatment should be their primary function. In this way more favourable conditions for

progress in relation to ætiology with consequent advances in the control and treatment of this widespread scourge would be made more effective.

(This Paper was illustrated by many clinical and X-ray photographs.)

Dr. G. D. Kersley: If osteo-arthritis is excluded from the discussion, the remainder of the rheumatic syndromes have certain points in common. They are all affections involving any or all of the mesodermal structures of the body and no others. All may apparently be caused by, or an attack be initiated by, a large number of common factors. In none of the syndromes has a specific infection been proven, though they are liable to occur during or after nearly any infection.

The only theory of ætiology which appears to cover the known facts is that rheumatism is caused by "an altered reaction of the macro-organism to an invasion by a foreign protein". Such a theory immediately raises four questions:

What is the altered reaction and what evidence is there that such a state exists; how can it be brought about and what are the foreign proteins which may be responsible?

(1) Supposing the altered reaction be classified as a type of sensitization, what does this necessitate immunologically? Sensitization is "a state of potential toxicity due to an intracellular antigen-antibody reaction". For this reaction to occur there are two requisites, namely, cell-fixed antibody and insufficient circulating antibody to neutralize the antigen.

(2) What evidence is there to suggest that such a state of sensitization occurs in rheumatism?

(*a*) Experimentally it has been shown (Roessle, 1936) that the local tissue reaction in sensitized animals is mesodermal only and resembles in many ways the rheumatic granuloma. Moreover, the reaction may be localized to a particular area by hyperæmia, trauma or fatigue (Klinge, 1929), frequent factors concerned in localizing rheumatic and gouty phenomena.

(*b*) Rheumatic pains frequently occur during the course of scarlet fever immunization (Rhoads and Afremow, 1943).

(*c*) When rheumatism develops as the apparent result of an infection there is usually a lag or incubation or sensitizing period of some two weeks between the onset of the infection and the first rheumatic symptoms.

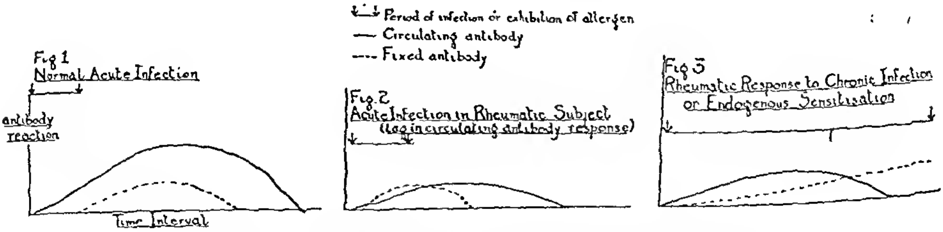
(*d*) Abnormally slow immune body response has been shown to occur when rheumatic subjects are infected with the hæmolytic streptococcus (Coburn and Pauli, 1939) and a similar slow response was suggested by Levinthal's work (1939) with yeast vaccines in rheumatoid patients.

(*e*) The response of some rheumatic conditions to salicylates and the absence of their response to sulphonamides or penicillin, except in long-continued prophylactic doses, can again be used as suggestive evidence in favour of a sensitivity factor in the rheumatic state.

(3) What factors may contribute in producing a susceptibility to sensitization? There may be a hereditary predisposition, best seen perhaps in gout and also in rheumatic fever, where Wilson suggests a mendelian factor is concerned. Alternatively, immunity, i.e. the presence of antibody in the blood-stream, may be depressed both by chronic infection, fatigue, exposure and climatic conditions and also by upset of the autonomic nervous system due to worry or shock—all common factors in initiating or aggravating the rheumatic state.

(4) What are the foreign proteins that may become antigenic in this sensitivity reaction? They may be exogenous in the shape of bacteria or their products, certain foods or even drugs (e.g. the sulphonamides) or in some cases they may perhaps be endogenous products liberated by physical microtraumata. Instances of the latter are chills, excessive fatigue and the repeated traumata which at first produce a monarticular arthritis. The arthritis may suddenly spread to many joints, taking on the character of a typical polyarthritis. The effect of such allergens is best exemplified and studied in the clear-cut attacks occurring in gout.

In the normal individual the response to infection consists of the production of antibodies in the serum before and in excess of any cell-fixed antibody (fig. 1). In "rheumatism" caused by acute infection or by a food or drug allergy, it is suggested that the serum antibody response is slow (Coburn and Pauli, Levinthal) so that, for a time, cell-fixed antibodies come into play causing an acute attack of arthritis or fibrositis (fig. 2). With a chronic infection or endogenous sensitization the immune body response may gradually become depressed so that the serum antibodies fall off, uncovering those that are fixed intracellularly, thus producing a chronic rheumatic state (fig. 3).



Fixed and circulating antibody curves resulting from an infection.

The above state of affairs, though to some extent hypothetical, does suggest certain obvious lines for further research and, possibly later, for treatment.

Dr. Ernest Fletcher stressed the point that rheumatic fever and rheumatoid arthritis may be extremely difficult to separate clinically and related a case in which it had been impossible to do so until the case came to autopsy.

With regard to the question of allergy in chronic rheumatism, he mentioned Cooke's recent work in which he described two types of clinical allergy, the "immediate" and the "delayed" type. In the immediate type the skin test becomes positive very rapidly and a passive transfer of skin-sensitizing antibodies occurs, i.e. Prausnitz-Kustner phenomenon is present.

The delayed type has a fairly constant incubation period but the skin test is negative and passive transference does not occur. Confusion between these two types has led to the use, and abuse, of skin tests and a good deal of error.

With regard to focal sepsis, the figures were very variable throughout the world but in a series of 254 cases of rheumatoid arthritis and 253 cases of osteo-arthritis, the percentage of cases rendered symptom free at the end of five years was 2·3 and 0·3.

Dr. W. R. Thrower said that he welcomed Dr. Kersley's contribution to the discussion because it was a real attempt to obtain an understanding of the essential pathology of rheumatism which for so long had been influenced by dogma and loose thinking. The fact that Dr. Kersley had suggested that rheumatic disorders were essentially a disturbance in mesoblastic structures was very reasonable when it was remembered that other embryological systems of the body had their own peculiar disorders, brought about usually by microbes which had a predilection for them. For instance, epiblastic structures were principally attacked by coccal infections and hypoblastic structures by bacillary infections. A reactive phase due to allergy or allied conditions might well occur in the mesoblastic system, the clinical features depending on which part was primarily involved. In the other disorders mentioned, localized manifestations often appeared, but the basic principle remained.

He hoped that this new concept of the rheumatic disorders might serve at least as a basis for a better understanding of the fundamental pathology of rheumatism to replace the numerous explanations now offered. It was only after a true appreciation of the cause of rheumatism that satisfactory control and treatment would be possible.

Dr. W. Annandale Troup: In my opinion one of the commonest causes of rheumatism in its various manifestations is chronic nasal catarrh and sinusitis. The profession as a whole quite erroneously informs the patient that there is no cure for these conditions and the patient drifts on from year to year using nasal drops and solutions in atomizers. Chronic nasal catarrh and sinusitis can be alleviated and cured by physical methods of treatment. By this I mean treatment by means of the Kromayer mercury vapour lamp and adjuvant physical methods. Over the last twenty years I have treated a great number of such cases. One invariably notes that the secondary toxæmic manifestations of rheumatism, which are invariably present in cases of long standing, subside and in the majority of cases disappear as the result of the successful treatment of the primary focus.

Operations for sinusitis, particularly if repeated, almost invariably lead to a lighting up of the rheumatic symptoms. The late Mr. Watson-Williams in his book "Chronic Nasal Sinusitis and its Relation to General Medicine" devotes several pages to chronic nasal sinusitis as an ætiological factor in the causation of various forms of rheumatism. Intestinal toxæmia, so frequently cited as a cause of rheumatism, is treated, but the chronic nasal catarrh which in many cases causes this is left untouched. Again, infected tonsils may be removed but the chronic catarrh which caused the infection is left untouched.

The enlightened treatment of chronic nasal catarrh and sinusitis would result in a marked reduction of the incidence of rheumatism.

Dr. W. Ganado: In brucellosis there is a very high incidence of arthritis, towards the end of the disease; indeed its occurrence before the sixth week is a rarity. This time-interval has suggested that sensitization is the cause of the arthritis, but the serum agglutinins are still at a high titre even when the arthritis occurs. It is possible that the antigen(s) causing the arthritis is different from the antigen producing agglutination. To argue from analogy is always unsafe especially when other presumptions are also involved. It is suggested that investigations on the ætiology of chronic rheumatism should include investigation for antigens that give other tests apart from agglutination.

ADDENDUM

SECTION OF MEDICINE—MEETING ON NOVEMBER 26, 1946

Discussion: "Birth Control: Some Medical and Legal Aspects"

The following paragraph was unavoidably omitted from the report of the Discussion in the *Proceedings* for December 1946, page 51, vol. 40.

Dr. Eustace Chesser: It is a disconcerting fact that doctors seem unable to consider, far less discuss, sex and contraceptive technique without their views being highly coloured by their own emotional make-up.

Mr. Green-Armytage has given us a very good example of "wishful thinking" when he states that in many Centres in the country, young girls are fitted with birth control "gadgets". Surely, he must be aware that nothing could be further from the truth.

Mr. Aleck Bourne is obviously not immune from this emotional bias—to wit his criticism of the Gräfenberg or silver ring. For example, what evidence has he for asserting that the ring acts as an abortifacient? Particularly when he himself states that he has delivered two women of full-term babies with the ring *in utero*?

What evidence has he for stating that the ring *per se* can produce a salpingitis? Surely, he must appreciate that such an infection can only be resultant on the *operation for the insertion of the ring.* If this is done with skilled hands, and under proper aseptic conditions, the risk of infection is certainly no greater than that following any minor operative procedure.

I think it is time it was realized that contraceptive technique is not merely a question of appliances or "gadgets"—but something much more subtle—personalities. In this mechanical age the latter fact has all too often been ignored.

Nutritional Liver Disease in West Indian Infants

By J. C. WATERLOW, M.B.

A DISEASE occurs among babies in the West Indies, whose main features are œdema, gross muscular wasting, and fatty infiltration of the liver. The onset is usually in the second six months of life, within three months of weaning. The presenting symptoms are vomiting and œdema. The œdema is of the hypoproteinæmic type, without albuminuria. The mortality of the disease is high and death appears to be due to hepatic failure. Analysis of the liver in fatal cases shows a fat content of up to 50% of the fresh weight. Hepatic functional impairment may be demonstrated during life by the bromsulphalein test. Other liver function tests, such as the colloidal gold test, and measurements of serum phosphatase, have given negative results. The presence of fatty infiltration can be confirmed by histological examination of liver tissue removed by aspiration biopsy.

This syndrome resembles closely the disease known in Africa as kwashiorkor, or infantile pellagra. In the African cases there are typically severe lesions of the skin and mucocutaneous junctions, and depigmentation of the hair—changes attributable to deficiency of riboflavin and of other members of the vitamin B_2 complex. The condition has generally been looked upon as the result of a mixed deficiency of protein and of B vitamins, and it has been suggested that the fatty liver is a manifestation of pellagra (Gillman and Gillman, 1945*a*) or of ariboflavinosis (Hughes, 1946). However, in the West Indian babies lesions of the skin, hair and mucosæ were seldom severe and were sometimes absent. In no case would the diagnosis of infantile pellagra be appropriate. In spite of this, the condition, judged by the mortality rate and by the degree of fatty infiltration of the liver, was no less severe than in Africa. This suggests that fatty liver in infants should be regarded as a disease *sui generis*, which may or may not be associated with signs of vitamin deficiency. For simplicity's sake it will be called the "fatty liver disease".

Certain objections have to be met before fatty liver in infants can be accepted as a specific entity. It is well known that severe fatty infiltration of the liver is found in infants dying of conditions such as gastro-enteritis or bronchopneumonia. But although the end-result may be the same in gastro-enteritis and in fatty liver disease, there may be a difference in the mechanism by which the fat accumulates in the liver. It is probable that in wasting diseases and in infections the fat in the liver is endogenous, derived from the body stores. It is suggested that in fatty liver disease the fat is exogenous, derived from the food. There is typically a history of feeding on a diet consisting mainly of starchy foods, low in protein and vitamins but with a high calorific value. Moreover, even in severe cases the fat depots are not entirely depleted; considerable quantities of subcutaneous fat are found at post-mortem. It is of interest that in the condition described by the German pædiatricians as "Mehlnährschaden" and attributed to overfeeding with carbohydrate, an intensely fatty liver has been observed (Huebschmann, 1921; Saito, 1924).

Overloading with calories is only one factor in producing fatty liver in these babies. It is generally agreed, and the evidence is very strong, that the underlying cause is a dietary deficiency of some kind. Experimentally the most widely studied type of dietary fatty liver is that produced by choline deficiency. The effects of choline deficiency can be prevented by methionine, which acts as a source of labile methyl groups. Inositol has a lipotropic action which is synergistic to that of choline. However, in babies with fatty liver, in the small number of cases tested in the West Indies, neither choline, methionine nor inositol appeared to have any effect in improving the condition of the liver or in saving life. Vitamin B_1, riboflavin, and nicotinic acid have been tried by workers in Africa with equally unsatisfactory results. On the other hand, good results have been obtained by the use of crude substances. Gillman and Gillman (1945*b*) in Johannesburg reported an excellent response to dried stomach. This has been both confirmed and denied (Trowell, 1946; Gelfand, 1946). In the West Indies it was found that a striking improvement occurred with no other treatment than an increased intake in milk. These results were controlled as far as possible by placing cases on a low milk intake for a preliminary period. On an intake of 7 to 8 oz. daily the condition remained more or less stationary; when the intake was increased to 30 oz. there was a rapid loss of œdema, a rise in serum protein concentration, and in dye clearance, and a more gradual decrease in the size of the liver. Serial biopsies showed a concomitant decrease in the severity of the fatty infiltration. No comparison is available between the effects of milk and of dried stomach. Our effort was directed to obtaining a base-line for the effects of milk alone, because all practical diets for babies must contain some milk. Until its action is known, it is impossible to investigate accurately the effectiveness of other substances. There is an urgent need for systematic fractionation and assay of the crude materials found effective. The isolation of an active substance which could be given parenterally would undoubtedly save many lives, since in severe cases oral treatment is made difficult by persistent vomiting.

All the evidence—the history, the associated lesions (hypoproteinæmic œdema and dermal and mucosal changes) and the response to treatment—suggests that the underlying deficiency in this fatty liver disease is either of protein or of some member of the vitamin B_2 complex; but it is not yet possible to choose between these alternatives. Reasons have already been given to suggest that neither riboflavin nor nicotinic acid is involved. Little is known about the possible rôle of the other B vitamins, apart from choline and inositol: but it is significant that good results in treatment have not been obtained with yeast. On the other hand, œdema is very constant in severe cases. There is gross macroscopic and microscopic wasting of muscles. Analyses of the liver in five fatal cases show a 20% decrease in the non-fatty solids, which are mainly protein. There is thus evidence of depletion in the three most important protein reservoirs of the body. Recent work on dogs (Fouts, 1943; Li and Freeman, 1946) has suggested a relation between protein deficiency and fatty liver. This type of fatty liver does not depend upon deficiency of methyl groups, since it is neither prevented nor cured by choline.

The cause of the fatty liver disease in infants is therefore still unknown. There is also much to be learnt about its natural history. In the course of the field investigations in the West Indies the question arose of how to recognize the disease in its early stages. In established cases that were responding successfully to treatment, it was found that the liver remains enlarged and, as shown by biopsy, still contains some fat for some time after the disappearance of the œdema and the restoration of normal serum protein concentration and dye clearance. It therefore seemed logical to suppose that in the development of the disease the reverse sequence occurs: that the first stage is a gradually increasing fatty infiltration and enlargement of the liver. Cases were found with enlargement of the liver but without other clinical or biochemical abnormalities, and with no evidence of malaria or syphilis. Biopsy of the liver in two such cases showed a moderate degree of fat, which was much decreased after one week on a high milk intake. This response to improved diet suggests that, in spite of the good clinical condition of the babies, fatty infiltration of the liver cannot be regarded as normal. It seems probable that such infants represent early or larval cases of the fatty liver disease, many of which become spontaneously cured. Babies with symptomless enlargement of the liver were common in the West Indies: they were more common in the second than in the first six months of life, which suggests that the enlargement was not merely an exaggeration of the physiological condition of the liver in the newborn.

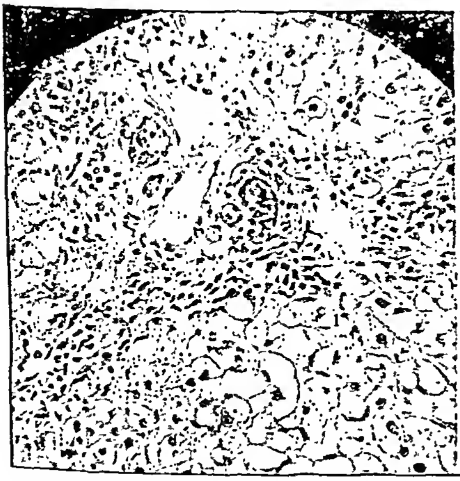

FIG. 1.

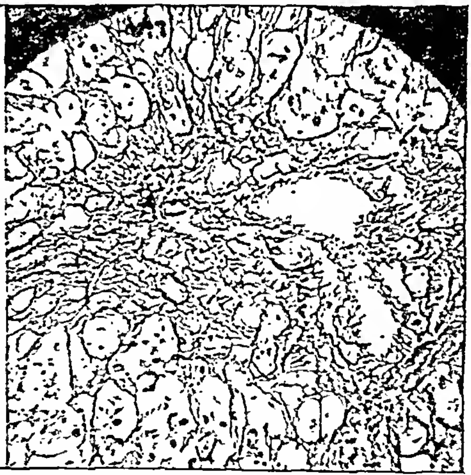

FIG. 2.

FIG. 1.—Liver. Biopsy specimen. Hæmatoxylin and eosin. × 187. There is cellular infiltration of the portal tract, and an increase of connective tissue. The liver contained no fat at the time that this biopsy was taken. The vesicular appearance of the hepatic cells is caused by the presence of glycogen. This specimen was taken from an infant aged 16 months, with enlargement of the liver, reduced hepatic function, œdema, and ascites.

FIG. 2.—As fig. 1. Silver impregnation (Gömöri's method) × 187. There is an increase of silver-staining fibres in the portal tract, and an outgrowth of fibres into the parenchyma, to form a fine network, surrounding some liver cells at the edges of the lobules.

In the age-group 6 to 18 months, definite enlargement of the liver (liver edge one fingerbreadth or more below the costal margin), not associated with signs of syphilis or enlargement of the spleen, was found in 10% of unselected infants. If the hypothesis outlined above is correct, then the fatty liver disease, at any rate in mild grades, must be regarded as a common condition in the West Indies. From the practical point of view, as regards prevention and treatment in infant welfare clinics, it might be said that enlargement of the liver without enlargement of the spleen is an indication for a supply of extra milk.

Finally, there is evidence that there may be late sequelæ in cases which neither die nor recover completely. In Jamaica cirrhosis of the liver in childhood is not uncommon. A series of cases was described by McFarlane and Branday (1945) with an average age of 5 years. Experimentally it has been shown both in rats (Lillie *et al.*, 1942) and in dogs (Chaikoff *et al.*, 1938) that fatty infiltration of the liver may proceed to cirrhosis. In human pathology, a similar sequence has been described in diabetes and in chronic alcoholism (Connor, 1938). It therefore seemed probable that cirrhosis of the liver in children in the West Indies might be the result of preceding fatty infiltration in infancy. An attempt was made to collect by means of liver biopsy pathological material to demonstrate this sequence of events. This material is as yet far from complete. The earliest change that has been seen is a thickening of the portal tracts, with round-cell infiltration and some proliferation of fibrocytes. This has been found in an infant 1 year old with a fatty liver of at least three months' standing. The next stage appears to be an outgrowth of reticulin fibres into the parenchyma from the portal tracts; these fibres penetrate between the hepatic cells at the edge of the lobule, and surround them. This has been seen in a child of 16 months (figs. 1 and 2). At a still later stage, some of the ingrowing fibres develop the histological characteristics of collagen, forming bands traversing the liver lobule. At this point the normal architecture of the liver begins to be destroyed. This pathological picture has been found in a child of 18 months with signs of portal destruction.

In rats, Himsworth and Glynn (1944) have described two types of dietary cirrhosis: in the first the fibrosis is diffuse, follows fatty infiltration and is caused by choline deficiency; in the second the fibrosis is coarse, follows massive necrosis, and is caused by deficiency of sulphur-amino-acids. In the infants described, the fibrosis was diffuse, with no sign of necrosis; there is therefore no resemblance to the second of the two sequences in the rat, and no reason to look upon sulphur-amino-acid deficiency as a possible cause.

Cirrhosis of the liver is much commoner in tropical than in temperate countries, with a high incidence in the fourth decade of life. Reports from all parts of the world show that this cirrhosis is predominantly of the diffuse Laennec type, often accompanied by fat. There is at present no evidence that "tropical cirrhosis" is a dietary disease: but the sequence of events that has been described in infants and children in the West Indies, which leads to an identical pathological picture may help to throw some light on its pathogenesis and cause.

The suggestions put forward in this paper are based on the preliminary findings in a small number of cases, and are therefore to be regarded as tentative, until supported by further evidence.

ACKNOWLEDGMENT

I am deeply indebted to the Directors of Medical Services in Trinidad, British Guiana and Jamaica for giving me facilities to work, and to numerous others in all three colonies for encouragement and help.

Dr. P. Ellinger: I fully agree with Dr. Waterlow that the condition he has described has nothing to do with real pellagra and I regret that by some authors it has been called infantile pellagra. Amongst hundreds of pellagra cases which I saw in Egypt in 1937 and 1938, as far as I can remember, there were no children below 4, the critical age of the nutritional liver disease. I examined in numerous villages of the Delta parts of the population selected at random. Amongst the people examined were numerous small children below 4 all of whom were free but pellagra was very frequent amongst children between 4 and 10 years.

I was also allowed to examine the post-mortem reports of the Department of Pathology of the Faculty of Medicine of the University of Cairo for reports on pellagrins. They were not very numerous but I could not find any remark on liver damage found in these pellagra post-mortems.

Some Renal Effects of Experimental Dietary Deficiencies

By H. Heller, M.B., Ph.D., and S. E. Dicker, M.D.

Dr. H. Heller: Liver lesions may be produced experimentally by feeding protein-deficient diets and it has been recently suggested (Himsworth and Glynn, 1944) that hepatic poisons act ultimately by reducing the supply of protective protein derivatives to the liver. Now many of the toxic factors which produce liver damage also give rise to lesions of the kidneys. The question arose, therefore, whether chronic protein deficiency may damage the kidney as well as the liver.

Following this idea it was decided to investigate the kidneys and the water metabolism of animals fed on various protein-deficient diets. The diet first used was modelled on the type of food which, in concentration and prison camps, has frequently been reported to lead to hypoproteinæmia and œdema, namely a protein-deficient vegetable diet of low calorific value. The supply of this diet which consisted essentially of raw turnips, starch, fat and adequate amounts of vitamins, was not restricted but its calorie value was so low that the amount eaten per animal per twenty-four hours provided only one-third of the number of calories supplied by the control diet. Other rats received a diet of the same composition but with fresh carrots taking the place of fresh turnips. These diets, while containing less than 0·9% of vegetable protein, contained sufficient amounts of choline to eliminate a deficiency of that substance.

Adult rats fed on the protein-deficient vegetable diets lost weight rapidly (about 35% of the initial body-weight in forty days). The mean plasma protein level fell from 7·6 to 4·7 grammes/100 c.c. in the same time. Externally there was little amiss. There was no diarrhœa. A sudden increase in body-weight occurring after a period of steady loss of weight was interpreted as due to accumulation of œdema fluid. The presence of ascites was subsequently verified in some of these animals. Ascites could also be frequently induced by giving 5% of the animal's weight of water by stomach tube. Diuresis experiments showed that only about half of the normal amount of water was excreted in the urine, thus confirming this tendency to water retention. Measurements of urinary specific gravity showed moreover that rats on the protein-deficient vegetable diets, where given 5 c.c. water/100 g. body-weight, were unable to dilute the urine to the same degree as before the institution of the experimental diet. Nor could such animals, where deprived of water for twenty-four hours, concentrate the urine as efficiently as normally, suggesting the possibility of renal tubular impairment.

This simple method of investigation can hardly be said to yield unequivocal evidence as to the functional state of the kidney. However, the application of renal clearance methods gave the following picture of kidney function in the rats on the protein-deficient turnip diet: The *inulin clearance* (used as a measurement of the rate of glomerular filtration) was significantly higher than in normal animals. It bore no clear relation to the plasma protein level but was significantly correlated with the rate of urine flow. The latter finding suggests that the rise of the filtration rate was not due to an increased permeability of the glomerular capillaries. The absence of protein in the urine of rats on the protein-deficient turnip diet agrees with this. *Diodone clearances* at high plasma diodone levels showed a pronounced decrease of the rate of tubular diodone secretion in the majority of the rats on turnip diet. It is difficult to ascribe the lowered rate of diodone secretion to anything but an impairment of renal tubular function. This interpretation was also adopted by Earle, Taggart and Shannon (1944) who observed similarly low values for diodone secretion in cases of human chronic glomerulo-nephritis.

The lowered capacity for tubular diodone secretion was not the only pathological feature of the kidneys of rats on "turnip diet". Histologically demonstrable lesions were present in the kidneys of many of these animals and the same type of injury was found in many of the rats on "carrot diet". The lesions consisted of necrosis and calcification of the broad limb of Henle's loop, the glomeruli and other parts of the tubules showing no apparent changes. However, there was no correlation between the incidence or severity of the lesions and the results of the diodone clearance tests, which suggests that the two phenomena should be regarded as different pathological entities.

The histological picture seen in these kidneys was quite different from the hæmorrhagic lesions produced in very young rats by choline-deficient diets (Christensen, 1942; Engel and Salmon, 1941). However, it resembled markedly the lesions produced by feeding small amounts of racemic serine to rats on protein-deficient diets (Morehead, Fishman and Artom, 1944). The latter observation confirms older work on the nephrotoxic effect of certain amino-acids (Newburgh and Curtis, 1928; Cox, Smythe and Fishback, 1929). It seems of particular importance in suggesting that a protein-deficient diet may lead to a diminished resistance of the kidneys to the injurious effects of "nephrotoxic" substances. It may well be that a similar mechanism underlies the production of the renal lesions observed in our rats. A similar phenomenon is well known in connexion with hepatic injuries. For instance, Miller and Whipple (1940) have shown that the hepatotoxic action of chloroform increases as protein stores decrease.

The hypothesis that the low calorie turnip or carrot diet diminished the resistance of the kidney to the necrotizing action of some unknown constituent (a particular amino-acid for instance) contained in the vegetables may thus explain the occurrence of renal lesions in our rats but it is by no means the only possibility. It seems equally possible that the renal lesions occurred because the vegetable protein administered lacked one or several of the essential amino-acids. Or again they may have been due to the insufficient supply of protein as such and to the resulting severe hypoproteinæmia. Finally, the low calorific value of the experimental diets must not be forgotten. The accelerated breakdown of endogenous protein and the increased production of their metabolic end-products may not be irrelevant.

A series of rats were fed on a diet which contained only 0·5% of casein, i.e. approximately as little protein as the vegetable diets. However, the starch content of this diet was higher and the animals lost weight more slowly than the "turnip rats". Renal function tests were performed when the degree of hypoproteinæmia became comparable to that in the animals on the vegetable diets. They showed the following results: The rate of glomeruler filtration was comparable to that of the turnip rats in that it was raised and correlated with the urine flow. Diodone clearances showed in many cases a much decreased rate of tubular secretion, again the same finding as in the turnip animals. However, histological investigation of the kidneys failed to show the typical necrotic lesions. These findings suggest once more that the impairment of renal tubular secretion, found in both types of protein-deficient diets, is not related to the histological findings. (This lack of relationship is perhaps not very surprising considering the view of Smith and his school that diodone is secreted by the proximal tubules and considering that the necrotic lesions found in our rats were limited to the broad limb of Henle's loop.) The results obtained in the "low casein" series suggest further that the low plasma protein level, as such, was not the main determinant for the occurrence of renal lesions in the rats which had been fed on the vegetable diets. However, a relative deficiency of "essential" amino-acids in these animals has not been excluded. It is one of the ætiological factors which still await investigation.

Dr. S. E. Dicker: Rats which had been fed on a protein-deficient vegetable diet for the same period and which had free access to water presented two different and contrasting pictures at post-mortem examination. Some animals had extremely "wet" tissues or even free liquid in the abdomen; others appeared abnormally "dry" with strikingly thin muscles. The decrease of the plasma protein level in the two groups was of the same magnitude. It was therefore thought of interest to examine whether, with reference to their water content, the tissues of the "dry" rats were essentially different from those of the rats with visible œdema.

When comparing the percentage of solids in plasma, muscle and liver of control rats with those of rats kept for sixty days on a vegetable diet, a significant decrease of solids in the tissues could be shown in both groups of the protein-deficient animals. The mean decrease of solids in the plasma amounted to 25·4%, that in the liver to 19·0%, but that in the muscle to 6·0% only. In other words, the increase in the total water content of muscle was much smaller than that in plasma or in the liver.

On the assumption that the cell membranes of rat muscle are impermeable to chloride, it is possible to calculate the extracellular fluid phase. By these means it could be estimated that the extracellular fluid phase of muscle of control rats amounted to a mean of 14·0 ml./100 grammes, that of the "dry" rats kept on the protein-deficient vegetable diet to 41·0 ml./100 grammes and that of the rats with visible œdema, fed on the same vegetable diet, to 55·0 ml./100 grammes.

It is thus clear that there was no essential difference between the two groups of hypoproteinæmic rats and that the "dry" animals suffered from occult œdema. It is therefore not surprising that the presence of visible œdema had no bearing on the outcome of the renal clearance tests.

DISCUSSION ON RADIOACTIVE TRACERS

Dr. A. S. McFarlane: One of the newer tools of physics about which much has been written in recent years is the cyclotron, a huge machine which whirls charged atoms around at ever-increasing speeds, and permits the physicist finally to hurl them at a target of his own choosing. If, as often happens, the whirling ion is that of deuterium, which has twice the mass of hydrogen, and the target is the metal beryllium, a radiation is given off by the beryllium which, like X-radiation, passes readily through the metal window of the cyclotron and has a powerful effect on a gold-leaf electroscope or on a photographic plate. Unlike X-radiation, however, it passes more readily through a sheet of lead than through a tank of water or a block of paraffin. This paradox—that more of the radiation gets through the denser medium—was resolved with many others by Sir James Chadwick when he showed that the beryllium radiates in fact a stream of uncharged particles each of virtually the same weight as a hydrogen atom and to which he gave the name neutrons.

If a piece of silver is held up to the stream of neutrons and is then taken into another room and brought near to an electroscope it will affect it much as did the original neutrons; it has in fact become radioactive. If the silver had been exposed instead to an X-ray beam it would have shown no radioactivity subsequently. The radioactivity of the silver does not remain constant but diminishes by half every two to three minutes so that after four to six minutes it is a quarter of the original value and after six to nine minutes one-eighth and so on. One might infer that the silver had stored up some neutrons and is giving them off again in its own time. However, the silver has little or no effect on the electroscope if a thin plate of metal is placed between the two, so clearly it is not giving off neutrons. It is not difficult to show that it is giving off electrons, the same light, negatively charged particles as are given off by radium. What has occurred is that each atom of silver, with a weight of 107 times the hydrogen atom, has captured one neutron so that its weight has increased to 108. Its chemical properties, however, are unchanged since these depend solely on the charge which of course is not affected by the acquisition of an uncharged particle. However, silver 108 is unstable and breaks down by giving off an electron of negligible weight. It therefore leaves behind cadmium 108 which has one positive charge more than silver. This is one example of a transmutation which takes place spontaneously as a result of our producing an unstable element.

It is, however, often quite easy to effect the transmutation directly by the action of neutrons. For example, if nitrogen in the form of an ammonium salt is exposed to the neutron beam it is converted into a radioactive form of carbon. It is an idiosyncrasy of the nitrogen atom, and of several others, that when it captures a neutron it does not feel at all happy and decides to throw out a hydrogen ion in exchange. The net result of this is to leave the atomic weight unchanged at 14, but a positive charge, which has been carried away by the hydrogen ion, is lost. Carbon 14 happens to have a half-life of 4,700 years—longer even than radium—and for this reason until recent years a visitor would observe around most cyclotrons, whatever they were being used for, a stack of bottles of ammonium nitrate set to catch stray neutrons. These would be left for months on end until a chemist came along and proceeded to extract a minute amount of carbon from all this salt, not demonstrably more than could be accounted for by the carbon impurity in the best grades of ammonium nitrate, but with radioactive properties.

To make the measurement of radioactivity more precise a device called a Geiger-Müller counter was developed and improved to such a degree that it will record the arrival of a single electron on a Post Office counter. There are some 10^{21}

atoms of silver in half a crown and when only one of these decides to change to cadmium the physicist can record the event with all the precision of a telephone call. The first samples of radioactive silver and carbon and other elements to be obtained were found to give out some hundreds of electrons per minute, corresponding to hundreds of atomic disintegrations per minute. However, bigger and better cyclotrons came along, followed by the uranium pile, which generates neutrons in fantastic quantities, and so the activities increased steadily until to-day samples of carbon are coming from the pile in one milligram of which one hundred million atoms of carbon disintegrate every minute. From a recent determination of the decay rate of carbon 14 by Reid and Dunning (1946) it is a simple matter to calculate that in one milligram of pure C^{14} rather more than ten thousand million atoms should disintegrate per minute, so that in these pile samples of carbon one part by weight in every hundred is the pure artificial element of atomic weight 14. There is no doubt that with further experience samples of 5% and even 10% purity will be available. But it is a relatively costly process and the present American price for 1 milligram of carbon containing about 10 micrograms of pure C^{14} is £100, which makes radium look comparatively cheap.

With some difficulty and the loss of at least half this valuable carbon an able chemist can prepare from it most of the metabolic substances in which we are interested containing a C^{14} atom in 1% of their molecules. Although an initial mg. of carbon gives off 10^8 electrons per minute in all directions it is only possible to collect a portion of these into the counter. In addition, since the electrons from carbon have very little energy some are absorbed by the counter window and altogether not much more than 10% of the electrons can be registered. Therefore, the count of the carbon in the substance prior to administration is found in practice to be reduced to about 5×10^6 per minute.

It is now known, largely as a result of isotope studies, that the body seldom makes use of exclusive metabolic pathways such as that by which iodine is built up only into the thyroid gland. Instead, most metabolic substances are attacked in a variety of highly specific ways affecting particular parts of the molecule. Amino groups are removed, carboxyl groups are oxidized and methyl groups are transferred from one substance to another, to give a few examples, and all at different rates. A group containing radio-carbon affected by one of these processes becomes mixed with the same group from molecules of other substances similarly affected, and the net result is that the specific radioactivity of the carbon in this group is reduced. If there are not many sources of the particular group the reduction will be small. In the worst case in which the carbon administered is in a hydrocarbon main chain it will be diluted with most of the carbon in the body. For an adult human being this means diluting our radio-carbon with roughly 5 kilos of tissue carbon, and if a 5 milligram sample of this is presented to the counter the C^{14} will show its presence by giving rise to 5 counts per minute, which is just about the lowest counting rate which is significant. If more than 5 milligrams of tissue carbon can be presented to the counter the accuracy will be proportionately greater. With laboratory animals a milligram of radio-carbon will clearly suffice for numerous experiments of this type. With humans the difficulty at present is that the safe dose of radio-carbon is not known with certainty, largely because of lack of knowledge of how long it persists in the tissues. As much as half a milligram of pure C^{14}, distributed uniformly throughout the body, may be permissible however.

If a sodium salt is placed in the neutron beam for a very short time and then presented to a counter it will give as many counts per minute as do the best samples of carbon. These counts come from sodium^{24} which has a half-life of only fourteen hours. The weight of pure Na^{42} present is immeasurable and yet we have an isotope preparation which will dilute as much as will 10 micrograms of pure C^{14} and still be detectable, because it disintegrates so quickly. Instead of costing £100 it is listed in America at a few shillings. It is detectable in a different way from C^{14} because in addition to electrons it emits (like radium) X-rays of the penetrating variety called γ-rays. It is possible, therefore, to measure the activity of Na^{24} with a sheet of metal in front of the counter or—of greater biological importance—with several centimetres of tissue between the source and the counter. Three minutes after drinking some radioactive sodium chloride it is sufficient to hold a hand in front of the counter and watch the rapid absorption into the blood-stream. This element when it becomes readily available should be of the greatest interest for measurements of the extra-cellular space and of electrolyte excretion.

Another -emitter is iodine^{131} of 8-days' half-life and costing three or four times as much as sodium. It can be detected in the thyroid by tucking the counter tube under the chin. This property is not possessed exclusively by γ-emitters. Some energetic electron emitters, e.g. radio-phosphorus, can be used for the same purpose, and Low-Beer (1946) claims to be able to detect local concentrations of radio-phosphorus in a breast carcinoma by superficial exploration with the counter. In general, however, the directional sense of the counters is poor on the one hand, and on the other the body seldom localizes elements with the degree of specificity which it shows towards iodine, phosphorus and calcium. A form of histochemistry is practised with the latter elements by placing a tissue section on a photographic plate, the radio-element revealing its position by causing a blackening of the plate.

Other radio-elements of potential or actual biological application are sulphur^{35} (half-life 88 days), chlorine^{36} (greater than 1,000 years), potassium^{42} (12 hours), calcium^{45} (180 days), iron^{55} (4 years) or ^{59} (47 days), arsenic^{76} (for use in toxicology and chemotherapeutics—26 hours), bromine^{80} (4½ hours), strontium^{85} (65 days), mercury^{197} (25 hours) or ^{203} (54 days), bismuth^{210} (5 days) and some very interesting inert gases for respiratory studies, e.g. argon^{41} (110 minutes) and xenon^{127} (34 days).

I would like to conclude with a brief reference to some important biochemical discoveries made with the use of isotopes. Twenty minutes after injecting subcutaneously a solution of sodium phosphate containing radioactive phosphorus the activity of the element in the plasma reaches a peak value and thereafter falls away very rapidly as the phosphate is taken up by the tissues. By giving diminishing quantities in spread injections it is possible to maintain an approximately constant level of radioactivity per milligram inorganic phosphorus in the plasma. During this period bone and other tissues, which take their phosphorus in inorganic form directly from the plasma, will receive phosphorus of constant specific activity and if the experiment goes on long enough the whole of the bone phosphorus will ultimately have this specific activity. For example rabbit epiphyseal bone phosphorus after seven weeks has an activity 30% of the plasma phosphorus showing that 30% of the bone phosphorus has been renewed in that time. By contrast one-quarter of the phospholipid in the liver is renewed in twelve hours (Hevesy and Hahn, 1940).

If we wish to know what proportion of the phosphorus in the fæces has been absorbed in the upper intestine and re-excreted in the lower it is only necessary to compare the specific radioactivity of fæcal phosphorus with that of the plasma or even the urine. The activity in the plasma is an equilibrium value determined by the rate at which inactive phosphorus arrives from the gut and radioactive from the injections. Phosphorus returned to the bowel comes from the plasma and must have the same specific activity before dilution with unabsorbed inactive phosphorus. The method is of course equally applicable to other dietary constituents.

This kind of work throws an altogether new light on the sites of formation in the body of many substances and on the speeds at which they are formed and broken down again. It reveals that the body is a complicated chemical factory, between constituent parts of which an incessant exchange of materials is taking place. This activity could not be suspected from the relatively desultory exchanges of food and excretory-products with the environment. Only by the use of elements chemically identical with the body elements, yet distinguishable physically, has it been possible to bring this to light.

Dr. E. E. Pochin: Dr. McFarlane has given us a very clear and full account of what radioactive isotopes are, how they are produced and estimated, and what inferences may be drawn from their use in metabolic investigations. I wish now to discuss the types of problem to which they have been applied successfully. They have been used over a very wide field of work which has increased rapidly during the war, both in the United States and at Copenhagen and Stockholm. This work has hitherto concerned physiology rather more than medicine, and the illustrations which I will give are drawn commonly from this field. They show, however, how powerful and versatile is this technique of investigation, and how widely and readily it is applicable to clinical problems. I will also discuss briefly the therapeutic uses of these isotopes, although they are not strictly covered by our title, on account of the potential scope and interest of this field of experimental medicine.

We may consider first the simplest case, in which the fate of an administered chemical element is followed throughout its subsequent molecular combinations in the course of normal intermediary metabolism. It has been found, for example, that not only plants, but also animal tissues can utilize carbon dioxide in the formation of carbohydrate. For, if carbon dioxide is administered to an animal in which the carbon atom is radioactive, it is subsequently found that samples of glycogen from the body contain this radioactive carbon, and the path of its synthesis has been studied in this way through an initial condensation with pyruvic acid to oxalacetic acid and on to carbohydrate.

The same form of examination can be carried a step further by analysing the rate at which certain metabolic products are formed. For example, when radioactive iodine is added to thyroid tissue slices, the labelled iodine rapidly passes into combination as diiodotyrosine, and at the end of three hours is already present to the extent of 12% as thyroxine (Morton and Chaikoff, 1943). Similarly, iron administered by mouth has been detected in formed hæmoglobin in five hours (Pommerenke and others, 1942).

It is particularly valuable to be able to study the rates of reaction or formation of compounds, the concentration of which is ordinarily maintained in a state of stable equilibrium in the body. It has hitherto been difficult to know whether, for example, a low iodine concentration in the thyroid was due to rapid output of thyroxine from the gland, or to an opposite condition in which iodine was only concentrated and released slowly by this tissue. If, however, a radioactive form of iodine is given by mouth, the rate at which this particular material enters the gland can be directly determined; or when administration is discontinued, the rate with which it leaves the gland can be found (Keating and others, 1945). By this method, which appears to be of wide and general application, the dynamics of a balanced reaction within the body can be directly studied. It will be noticed that this can be done while giving only a small or normal intake of iodine during the course of the investigation. This is in contrast with the only method available hitherto, in isotope preparation which will dilute as much as will 10 micrograms of pure C^{14} and still be detectable, because it disintegrates so quickly. Instead of costing £100 it is listed in America at a few shillings. It is detectable in a different way from C^{14} because in addition to electrons it emits (like radium) X-rays of the penetrating variety called γ-rays. It is possible, therefore, to measure the activity of Na^{24} with a sheet of metal in front of the counter or—of greater biological importance—with several centimetres of tissue between the source and the counter. Three minutes after drinking some radioactive sodium chloride it is sufficient to hold a hand in front of the counter and watch the rapid absorption into the blood-stream. This element when it becomes readily available should be of the greatest interest for measurements of the extra-cellular space and of electrolyte excretion.

Another -emitter is iodine^{131} of 8-days' half-life and costing three or four times as much as sodium. It can be detected in the thyroid by tucking the counter tube under the chin. This property is not possessed exclusively by γ-emitters. Some energetic electron emitters, e.g. radio-phosphorus, can be used for the same purpose, and Low-Beer (1946) claims to be able to detect local concentrations of radio-phosphorus in a breast carcinoma by superficial exploration with the counter. In general, however, the directional sense of the counters is poor on the one hand, and on the other the body seldom localizes elements with the degree of specificity which it shows towards iodine, phosphorus and calcium. A form of histochemistry is practised with the latter elements by placing a tissue section on a photographic plate, the radio-element revealing its position by causing a blackening of the plate.

Other radio-elements of potential or actual biological application are sulphur^{35} (half-life 88 days), chlorine^{36} (greater than 1,000 years), potassium^{42} (12 hours), calcium^{45} (180 days), iron^{55} (4 years) or ^{59} (47 days), arsenic^{76} (for use in toxicology and chemotherapeutics—26 hours), bromine^{80} (4½ hours), strontium^{85} (65 days), mercury^{197} (25 hours) or ^{203} (54 days), bismuth^{210} (5 days) and some very interesting inert gases for respiratory studies, e.g. argon^{41} (110 minutes) and xenon^{127} (34 days).

I would like to conclude with a brief reference to some important biochemical discoveries made with the use of isotopes. Twenty minutes after injecting subcutaneously a solution of sodium phosphate containing radioactive phosphorus the activity of the element in the plasma reaches a peak value and thereafter falls away very rapidly as the phosphate is taken up by the tissues. By giving diminishing quantities in spread injections it is possible to maintain an approximately constant level of radioactivity per milligram inorganic phosphorus in the plasma. During this period bone and other tissues, which take their phosphorus in inorganic form directly from the plasma, will receive phosphorus of constant specific activity and if the experiment goes on long enough the whole of the bone phosphorus will ultimately have this specific activity. For example rabbit epiphyseal bone phosphorus after seven weeks has an activity 30% of the plasma phosphorus showing that 30% of the bone phosphorus has been renewed in that time. By contrast one-quarter of the phospholipid in the liver is renewed in twelve hours (Hevesy and Hahn, 1940).

If we wish to know what proportion of the phosphorus in the fæces has been absorbed in the upper intestine and re-excreted in the lower it is only necessary to compare the specific radioactivity of fæcal phosphorus with that of the plasma or even the urine. The activity in the plasma is an equilibrium value determined by the rate at which inactive phosphorus arrives from the gut and radioactive from the injections. Phosphorus returned to the bowel comes from the plasma and must have the same specific activity before dilution with unabsorbed inactive phosphorus. The method is of course equally applicable to other dietary constituents.

This kind of work throws an altogether new light on the sites of formation in the body of many substances and on the speeds at which they are formed and broken down again. It reveals that the body is a complicated chemical factory, between constituent parts of which an incessant exchange of materials is taking place. This activity could not be suspected from the relatively desultory exchanges of food and excretory-products with the environment. Only by the use of elements chemically identical with the body elements, yet distinguishable physically, has it been possible to bring this to light.

Dr. E. E. Pochin: Dr. McFarlane has given us a very clear and full account of what radioactive isotopes are, how they are produced and estimated, and what inferences may be drawn from their use in metabolic investigations. I wish now to discuss the types of problem to which they have been applied successfully. They have been used over a very wide field of work which has increased rapidly during the war, both in the United States and at Copenhagen and Stockholm. This work has hitherto concerned physiology rather more than medicine, and the illustrations which I will give are drawn commonly from this field. They show, however, how powerful and versatile is this technique of investigation, and how widely and readily it is applicable to clinical problems. I will also discuss briefly the therapeutic uses of these isotopes, although they are not strictly covered by our title, on account of the potential scope and interest of this field of experimental medicine.

We may consider first the simplest case, in which the fate of an administered chemical element is followed throughout its subsequent molecular combinations in the course of normal intermediary metabolism. It has been found, for example, that not only plants, but also animal tissues can utilize carbon dioxide in the formation of carbohydrate. For, if carbon dioxide is administered to an animal in which the carbon atom is radioactive, it is subsequently found that samples of glycogen from the body contain this radioactive carbon, and the path of its synthesis has been studied in this way through an initial condensation with pyruvic acid to oxalacetic acid and on to carbohydrate.

The same form of examination can be carried a step further by analysing the rate at which certain metabolic products are formed. For example, when radioactive iodine is added to thyroid tissue slices, the labelled iodine rapidly passes into combination as diiodotyrosine, and at the end of three hours is already present to the extent of 12% as thyroxine (Morton and Chaikoff, 1943). Similarly, iron administered by mouth has been detected in formed hæmoglobin in five hours (Pommerenke and others, 1942).

It is particularly valuable to be able to study the rates of reaction or formation of compounds, the concentration of which is ordinarily maintained in a state of stable equilibrium in the body. It has hitherto been difficult to know whether, for example, a low iodine concentration in the thyroid was due to rapid output of thyroxine from the gland, or to an opposite condition in which iodine was only concentrated and released slowly by this tissue. If, however, a radioactive form of iodine is given by mouth, the rate at which this particular material enters the gland can be directly determined; or when administration is discontinued, the rate with which it leaves the gland can be found (Keating and others, 1945). By this method, which appears to be of wide and general application, the dynamics of a balanced reaction within the body can be directly studied. It will be noticed that this can be done while giving only a small or normal intake of iodine during the course of the investigation. This is in contrast with the only method available hitherto, in which the level of the equilibrium needed to be measurably disturbed by giving a large dose of normal iodine which in itself upset the metabolism of the gland that it was designed to investigate. It has been found in a similar way that iron absorption from the gut is considerably increased, not by anæmia itself, but by depletion of the iron stores within the body. Thus in anæmia of acute onset the efficiency of iron absorption is not increased until about a week after the initial hæmorrhage (Hahn and others, 1943).

So far, we have discussed the use of tracer materials to study the course of chemical reactions and their progress in time. It is also possible by similar methods to study the rate of diffusion of materials throughout the body in just the same way as the ornithologist, who catches and rings a collection of swallows in Kent, can study the rate and route of their migration by the appearance of such "labelled" birds in different places and at different times subsequently. It is, of course, essential that the ring on the bird's leg shall not alter its powers of flight, and in exactly the same way it is essential that the radioactivity of the tracer material shall not in itself alter its metabolism or that of the tissue studied. In this way, the rates of diffusion of sodium and other materials into the cerebrospinal fluid or the aqueous humour of the eye or from the intestinal tract have been investigated, and the method is clearly applicable to a wide range of drugs or toxic materials of clinical interest. The transfer of iron to the bile in hæmolysis, or from the maternal blood-stream to the fœtus (Pommerenke and others, 1942), has been similarly investigated and studies have been made on the rate of absorption of substituted insulin molecules from the skin when given in different forms designed to delay absorption (Reiner and others, 1943).

It is a simple matter by these means to investigate the extent within the body through which various compounds or structures are free to diffuse. For example, the blood volume has been estimated, by giving a known amount of red cells labelled with either radioactive iron or phosphorus and, after allowing time for mixing, determining the concentration of such red cells in the sample removed, and therefore the volume within the body throughout which the total amount of cells given has been distributed. It is clearly a necessity of such an investigation that the labelling element, which is here used to mark the red cell, must remain permanently attached to that cell during the course of the experiment. This assumption appears to be sound for studies of blood volume. When, however, the length of survival of administered red cells was explored in this way, it was soon found that the iron from cells as they became destroyed was rapidly and fully utilized, after a lag of only a day or two, in the formation of new red cells within the recipient. It is therefore possible by this method to study only the initial stages of blood destruction since thereafter some of the radioactive iron is now attached to and labelling newly formed red cells. This type of criticism requires consideration in all investigations where an isotope is used to label a molecule or tissue structure.

Similarly, studies have been made on the space through which plasma proteins diffuse, by labelling these compounds in various ways. It is then found that a test dose of plasma proteins after administration rapidly becomes diffused through a space greater than the plasma volume itself by about fourfold (Fink and others, 1944). The distribution of sodium and other ions throughout the body has been similarly studied, and the absorption of inert gases in body tissues was closely investigated during the war. The last method has a possible application of considerable importance. If radioactive krypton is breathed in air of constant composition, the blood rapidly attains a constant content of radioactivity. If now the hand is placed under a Geiger counter, the radioactivity measurable within the hand as a whole is at first a measure of the amount of blood within the hand and only later of the amount of krypton which has diffused from the blood into the tissues. During the early stage, therefore, the total estimated activity within the hand is an index of its blood content, and the initial rate of increase of such activity gives an index of blood flow. It seems likely that this method may be of application in measuring the blood flow of a variety of tissues.

It will be noticed that we have been discussing a case in which the concentration of a radioactive isotope is measurable without withdrawing a sample from the body, and it is a particularly valuable feature of certain isotopes that their emissions are sufficiently powerful to be detected through the normal skin. This has been used in many ways, for example to determine circulation times between certain points, and in measuring the rate with which normal and pathological thyroids concentrate iodine.

A somewhat similar technique allows the distribution of certain elements within the tissues to be accurately studied by tissue slices or in histological sections. Since the emissions of many of these isotopes cause exposure of an X-ray film, if a film is placed in contact with a section or the tissue slice and is subsequently developed, the areas of blackening correspond to the areas in which the isotope is present or is concentrated. The distribution of administered calcium within rachitic bone has been explored in this way and the correspondence in thyroid tissue between the location of iodine and acinar cells can be similarly investigated. This method is well illustrated in Hamilton's review of the use of radioactive isotopes (1942).

Finally, the effect of these emissions can be used therapeutically in two ways. First, the easy production of large quantities of radioactive isotopes which is promised by the modern pile will allow cheap substitutes for radium to be produced in large quantities. It will be simple within a few years to obtain, for example, a radioactive cobalt with γ radiation rather harder than that of radium, and with β radiation rather more easily filtered. It would also be possible, owing to the hundreds of radioactive isotopes which exist, to select particular ones of emission and half-period suitable for particular problems.

Secondly, however, and of even greater interest, it will be possible in certain cases to use radioactive elements in producing selective irradiation of particular pathological tissues, while giving a greatly lower dosage of radiation to the body as a whole. Thus, if an element such as iodine is concentrated in the thyroid to a degree a hundred times greater than in the rest of the body, and if a radioactive iodine is given, of which most of the radiations penetrate only a short distance, a dosage within thyroid tissue can be obtained a hundred times greater than that in the rest of the body. In this way, a malignant thyroid carcinoma with metastases has been given a sufficient dose to cause its regression and possible cure (Seidlin, Marinelli and Oshry, 1946). This dose given to the whole body would cause death through radiation sickness. Iodine has been used in this way to produce controlled atrophy of most of the over-acting gland in thyrotoxicosis. Use has also been made of the fact that phosphorus is concentrated three times as highly in certain malignant tissues as it is in the body generally. Cases of leukæmia, multiple myeloma, and lymphosarcoma have been treated in this way, but without appreciably greater success than is obtainable with X-rays. Such opportunities for therapy may, however, develop with increasing knowledge of the concentration ratios in certain tissues and tumours of rare or hitherto unimportant metals or elements, or by the use of special devices such as the administration of radiobrominated dyes or insoluble chromic phosphate particles which are concentrated within the reticulo-endothelial system.

The whole study of concentration ratios of the lesser-known elements is likely to prove of great importance not only in therapy but in the safety of investigational methods. It is simple to calculate a dose of radioactive isotope which can safely be given to man without causing appreciably more ionizations within the body than are already caused by cosmic radiation each day, provided that it can be assumed that this material will not be selectively concentrated in some vital region. If, however, any such concentration occurs, a toxic level may be reached locally, although the average for the body as a whole is entirely harmless. While such an event appears unlikely in many instances, and has not been recognized in the many investigations made on man in the States and in Scandinavia, it is an important possibility to be excluded, particularly when a new element is being used. It should also be remembered that the effects of radiation on genes and chromosomes occur without threshold, and in proportion to the ionizations received, so that it is not possible to speak of a dose which is without biological effect, but merely of one in which this effect is comparable with those ordinarily received in daily life. With this proviso, and assuming that the radioactivity of the isotope given does not alter the metabolism of the tissues studied, it will be clear that the use of radioactive isotopes offers a very wide field in investigating biological and clinical phenomena.

Professor A. St. G. Huggett: When will these tracer elements be available? How does one obtain them?

Dr. McFarlane: The Medical Research Council has set up an advisory sub-committee in connexion with this matter and requests from any source in this country for tracers for biological and medical purposes should be made to the Secretary of the Tracer Element Sub-Committee at the National Institute for Medical Research, Hampstead.

At the moment numerous people are waiting to receive radio-elements—mainly phosphorus, iodine, iron, and sodium—but only phosphorus is available. This comes in small consignments monthly from the U.S.A. and has so far proved adequate to the needs of eight to ten research projects. Because of the much larger amounts used in therapy, no radio-elements have so far been available for this purpose. It is hoped in one to two months' time to be able to obtain steady cyclotron supplies in this country and later larger quantities of most radio-elements are expected to be available.

Professor H. P. Himsworth: What arrangements have been made for the analysis of biological material after giving stable and radioactive isotopes?

Dr. McFarlane: The Medical Research Council has been allocated 50 Geiger counting outfits of recent design by the Atomic Energy Research Establishment at Harwell. Some of these have been delivered and all but a few are already allocated—to laboratories widely scattered throughout the country. Several firms are also offering counting outfits for sale. Stable tracer elements are also available, but their assay with the mass spectrometer is a much more formidable proposition. Several of these instruments are under construction in this country, although only two or three with biological estimations in view. One will soon be completed at the National Institute for Medical Research.

DISCUSSION ON STRESS INCONTINENCE IN MICTURITION

Mr. Everard Williams: Stress incontinence is an acquired lesion of traumatic origin occurring in women in whom the function of micturition was previously normal. This definition will exclude cases of congenital origin, such as are met with in association with spina bifida, epispadias, and other gross congenital deformities. It will likewise exclude those due to degenerative changes which occur in later life, such as subacute degeneration of the cord, disseminated sclerosis and the like.

The absence of the prostate, the presence of the vagina and the different function of the urethra in women call for a difference in morphology from that which appertains to the male. To Kalisher we owe the first clear and accurate description of the anatomical points concerned. In 1900 he demonstrated the points of difference in the two sexes.

Apart from the general factors involved in maintaining the pelvic viscera in position, the localized supports of the bladder are concentrated around the urethro-vesical juncture. It is at this point that the vesical and vaginal fascias fuse, and fuse so intimately that they cannot be separated by dissection.

Furthermore, from the sides of the pelvis the lateral true ligaments of the bladder, anterior extensions of Mackenrodt's ligaments, and the anteriorly placed pubo-vesical ligaments, all become intricately blended at this point.

Kalisher further showed that the old description of the internal urethral sphincter was incorrect. The internal sphincter muscle consists of both circularly and longitudinally arranged muscle fibres. The circular fibres are not in the form of a completely encircling muscle, but are deficient anteriorly so that they have the arrangement of a sling which, in contraction, raises the floor of the urethra and holds it against the roof. They are arranged in two layers which embrace the longitudinal muscle fibres which are found in the floor of the urethra only. The longitudinal muscle fibres in their contraction depress the trigone and pull the floor of the urethra away from the roof. This disposition of fibres takes place at the point where the pubo-vesical ligaments find their insertion into the vesical fascia. The nerve supply of these differently arranged fibres is autonomic, parasympathetic stimulation relaxes the circular fibres and contracts the longitudinal fibres; sympathetic activity has the opposite effect. In contrast to what is found in the male the external sphincter muscle is of weak development and many of the muscle fibres do not encircle the urethra, but are lost in the vaginal walls. [Slides were shown from dissections on the cadaver illustrating these points.]

This description has been accepted by the leading continental gynæcologists, but is not found in British textbooks.

In the condition of stress incontinence descensus has taken place in the region of the bladder neck. The usual cause is a childbirth injury, or, less frequently, a gynæcological operation, such as hysterectomy.

Cases following operation are the more difficult to cure.

If the laceration of fascia includes the main mass of Mackenrodt's ligament as well as its anterior extension, there will be prolapse of the utero-vaginal canal in addition to the descensus of the bladder neck.

The physiology of micturition is less well understood than the anatomy. There are known to be five reflexes concerned in voluntary voiding; four are located in the spinal cord and the fifth is situated in the hind brain.

All research workers observe that the sphincter mechanism is exceedingly delicate and that in the experimental animal it responds to an increase in intravesical *tension*, not to intravesical *volume*. That is to say, a small volume of fluid rapidly introduced will cause the sphincter to open, whereas the bladder will tolerate a large volume, provided the fluid is very gradually introduced. In the cat, division of both pubic nerves (which carry no autonomic fibres) causes the appearance of stress incontinence. If the animal jumps, or is made to leap into the air, there is a small involuntary escape of urine accompanying the muscular action. (*See* "Central Nervous Control of Micturition", by F. J. F. Barrington, 1928, *Brain*, 51, 209.)

The establishment of the diagnosis and the methods of examination are well known. I shall mention only the necessity for complete urological and neurological investigation in all cases.

In order to assess the merits of the different operations, and to define their proper places, it is helpful to have some classification of the degree of severity of the lesion.

Stoeckel suggested a classification into four different categories, but I have adopted the simple division into mild and severe, omitting the transient cases in the puerperium which right themselves spontaneously (though they may be assisted by electrical therapy) and on which no surgeon would operate.

Mild cases are those in which a sudden great increase of abdominal pressure such as a cough, a laugh, a sneeze, brings about the incontinence.

Severe cases are those in which a slight increase of abdominal pressure, such as walking dowstairs, walking downhill, or the mere change of body posture, produces incontinence.

[A historical review of the different operations was given, but is omitted on account of the shortage of space.]

What is the feature common to all the operations employed in the alleviation of the condition? It is the raising of the trigone area of the bladder and the anchoring of it in the raised position. It is not the suture of a tear in the vesical fascia, nor of a torn sphincter muscle albeit distinguished surgeons have expressed the view that this is what their operation achieves.

There is a simple and more direct way of accomplishing this effect upon the trigone. With this object in view I devised and performed a new operation in 1942.

Author's operation.—With the patient in the Trendelenburg position and suitably anæsthetized, the abdominal wall is incised, but the peritoneum is not opened. Transversalis fascia is incised and the bladder exposed. The dissection is continued by light scalpel cuts until the bladder is well mobilized and the region of the neck freely exposed. The bladder wall and the investing fascia are now held in tissue forceps and traction is made to ascertain that the mobilization is adequate. By means of a fully curved needle and non-chromic catgut, the bladder wall, consisting of muscle and fascia, is sutured to the fibrous periosteum at the back of the pubis by four, or more, sutures placed in pairs on either side of the mid-line (*see* figs. 1, 2, 3, 4). If this has been correctly carried out, it will be seen on examination at a later date that the vestibule has retracted within the tissues of the vulva as is normally the case and the pathological laxity in this region has disappeared.

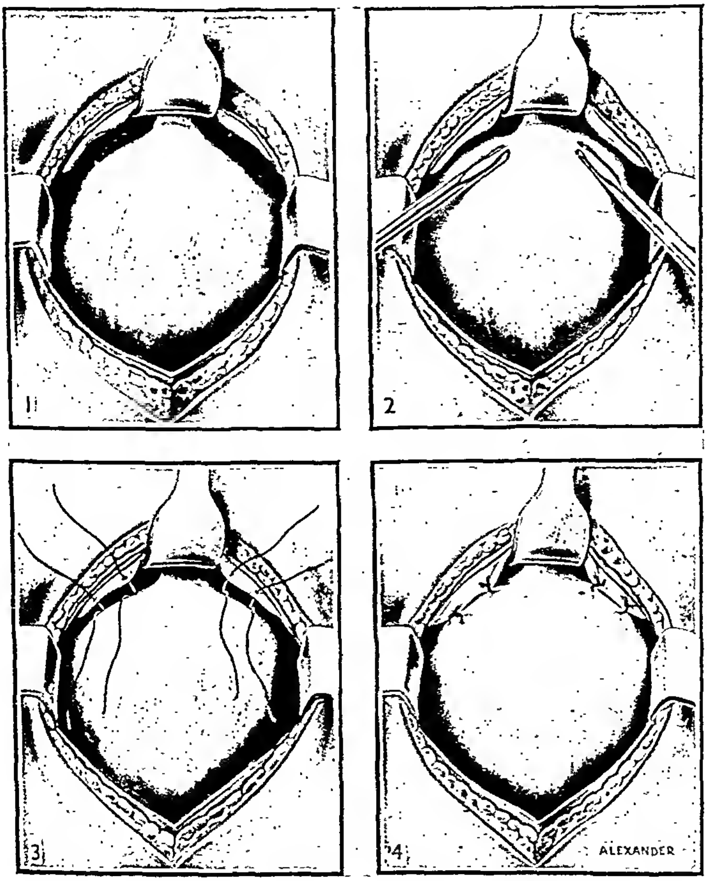

Fig. 1.—Exposure. Fig. 2.—Mobilization.
Fig. 3.—Suture. Fig. 4.—Restitution.

The bladder is not opened and the abdominal wall is closed in the usual way. A self-retaining catheter is employed for five days, and the bladder kept empty. The operation is followed by a period of difficult micturition and mild bladder irritability, but the bladder function quickly returns to normal.

The table shows the nine cases in which the operation has been performed by me since 1942. The interval 1943—1945 is explained by my absence on war service.

SEVERE CASES

No.	Name	Age	Date of operation	Last report	Comments
1	G. B.	55	Sept. 1942	2.11.46	Still perfect. 4-year cure
2	——		Cannot be traced		——
3	M. S.	40	28.8.45	18.3.46	3 para.; last 8 years ago. Forceps. S.I. since
4	H. N.	39	28.8.45	1.3.46	20 years S.I. following 1 confinement
5	M. M.	24	—.2.46	—.10.46	Extended breech "some years ago." Perfect result—4 mo. gravid.
6	E. H.	43	20.3.46	6.11.46	S.I. since birth of 2nd child 8 years ago. Asthma and ch. bron. Marion operation failed.
7	M. F.	40	—.5.46	—.10.46	1 para. 16 years ago extended breech. Fractured humerus and brachial palsy
8	E. M.	37	21.5.46	—	11 years S.I. following 1 confinement. Forceps delivery.
9	H. B.	40	—.8.46	—.10.46	Cured so far. Forceps delivery 20 years. ago. S.I. since confinement

There is one four-year cure and one case (No. 11) in which there was recurrence after eight months. The latter was a subject of severe asthma and chronic bronchitis, and during these eight months a mild degree of utero-vaginal prolapse had become accentuated.

POSTSCRIPT.—(i) A Fothergill repair has since been performed on this patient.

(ii) Case 5 (M. M.) has recently been delivered of a healthy baby; she remains cured.

Mr. Terence Millin: There are four main types of stress incontinence: (1) Congenital sphincteric weakness. (2) Post-puerperal, which will frequently go on to spontaneous recovery, and often benefited by faradic stimulation. (3) Menopausal, which may respond to hormone therapy. (4) The commonly met with stress or orthostatic incontinence, usually coming on some years after childbirth, and commonly associated with vaginal laxity.

My interest in the subject dates back more than ten years, when I first met a group of young girls suffering from a congenital form of urinary incontinence not due to any apparent neuropathy. For obvious reasons vaginal intervention was to be avoided, and I searched the relevant surgical literature without getting much help. Cysto-urethroscopic investigation of these cases revealed in all a patulous bladder neck, and I evolved and practised the intravesical tautening operation, which I described to the Section of Urology in January 1939 (*Proc. R. Soc. Med.*, **32**, 777). This entailed a generous excision of the posterior lip of the bladder neck, with a wedge running into the upper urethra. The cut edges of urethra and bladder neck were then approximated snugly around a No. 4 catheter, which was then removed, and suprapubic drainage maintained for ten days.

The results in these congenital cases were so gratifying that when confronted with a multipara who had undergone three vaginal interventions without cure of her stress incontinence, I applied this intravesical operation combined with a Goebell sling of ribbon catgut with complete cure. I operated upon more than a score of such cases by this technique with satisfactory results on the whole. Here is an illustrative case: Mrs. C., aged 38, still suffering from marked stress incontinence, almost complete, despite a colporrhaphy. Intravesical operation with immediate complete cure. Two years post-operatively she developed a severe attack of whooping-cough, and, despite this, there was no incontinence. Now five years post-operatively she remains a complete cure.

Despite such results, I felt that it should not be necessary to open the bladder in the acquired type of case, as there was seldom any apparent intrinsic bladder-neck deficiency, and the intervention was followed sometimes by a troublesome basal cystitis. I lacked the courage at first to abandon the intravesical tautening, but shortened the period of suprapubic drainage, and added a fixation of the bladder neck to the tendons of the recti close to the pubis in an attempt to draw up and fix the ptotic structure. This differed from the ventrofixation of the bladder employed many years ago by Victor Bonney in selected cases. His operation had the demerit of fixing the elastic anterior bladder wall which stretches so that this operation does not give lasting results. This idea of fixing the bladder neck to the back of the pubis has recently been revived by Perrin of Lyon, and has been termed cervico-cystopexy. I feel that there is always the risk of perforating the mucosa, and of the thread or silk becoming a nidus for phosphatic deposits.

Convinced that the essential requirement for cure was elevation of the bladder neck I devised my "muscle hammock" or "sling" operation, which I have now used for more than two and a half years with great satisfaction. The Goebell operation and its various modifications, notably those of Stoeckel and Frankenheim, did not appeal owing to the difficulty of assessing the exact degree of tension required in the sling, as one end was attached to a fixed bony point, namely the pubis, the free end being fastened to the aponeurosia. Undue tension would lead to dysuria, or even retention, and insufficient tension to a complete or partial failure. My idea was to elevate and suspend the bladder neck by a sling supported at each end to muscle, so allowing for a variability of tension. By relaxing the abdominal wall as in the normal position adopted for micturition, the sling would be relaxed, and on tightening the abdominal wall, as inevitably occurs when the intra-abdominal pressure rises as in coughing, sneezing, running, &c.—the precise factors causing a stress incontinence—the sling is actually tightened, and the bladder neck drawn upwards.

Before giving the details of this operation I shall briefly review the other procedures in use. They may be grouped roughly thus:

(1) The vaginal operations of Kelly, Bonney, Marion, &c., which aim at elevating the bladder neck by buttressing this structure from below by gathering in the stretched or torn subjacent fasciæ. The Kelly school believe that the sphincter must be reefed at the same time, but my cysto-urethroscopic studies and experience with the intravesical operations for the condition showed no intrinsic sphincteric laxity. I cannot confirm the findings of Macky, who claimed to show the torn ends of the sphincter intravesically and to suture them. Kennedy of New York, who has given much thought to the problem (describing incidentally various urethral sphincters), believes that it is necessary to free extensively the bladder neck and urethra from the back of the pubis. He then plicates the urethra and approximates the fasciæ. His procedure is supported by Counsellor of the Mayo Clinic. Others, however, maintain that this operation is unnecessarily heroic, and stress that very troublesome bleeding can occur, necessitating packing. Be that as it may, Kennedy's concept of the underlying pathology—namely a bladder neck that is dropped and, as he thinks, fixed in its false position—is similar to mine.

(2) The second group of operations are those which rely on narrowing the urethra. Into this group fall the rotations of the urethra, which I feel, in common with most workers, should be condemned whole-heartedly. Lowsley of New York frees the urethra on its anterior aspect, and plicates the bulbo-cavernosi muscles with ribbon catgut. The anatomo-pathology underlying this procedure is difficult to see. Others, following Giordano, use gracilis or part of it, to lap the urethra, but such operations also fail to recognize the essential pathology underlying the condition.

SEVERE CASES

No.	Name	Age	Date of operation	Last report	Comments
1	G. B.	55	Sept. 1942	2.11.46	Still perfect. 4-year cure
2	———		Cannot be traced		———
3	M. S.	40	28.8.45	18.3.46	3 para.; last 8 years ago. Forceps. S.I. since
4	H. N.	39	28.8.45	1.3.46	20 years S.I. following 1 confinement
5	M. M.	24	—.2.46	—.10.46	Extended breech "some years ago." Perfect result—4 mo. gravid.
6	E. H.	43	20.3.46	6.11.46	S.I. since birth of 2nd child 8 years ago. Asthma and ch. bron. Marion operation failed.
7	M. F.	40	—.5.46	—.10.46	1 para. 16 years ago extended breech. Fractured humerus and brachial palsy
8	E. M.	37	21.5.46	—	11 years S.I. following 1 confinement. Forceps delivery.
9	H. B.	40	—.8.46	—.10.46	Cured so far. Forceps delivery 20 years ago. S.I. since confinement

There is one four-year cure and one case (No. 11) in which there was recurrence after eight months. The latter was a subject of severe asthma and chronic bronchitis, and during these eight months a mild degree of utero-vaginal prolapse had become accentuated.

POSTSCRIPT.—(i) A Fothergill repair has since been performed on this patient. (ii) Case 5 (M. M.) has recently been delivered of a healthy baby; she remains cured.

Mr. Terence Millin: There are four main types of stress incontinence: (1) Congenital sphincteric weakness. (2) Post-puerperal, which will frequently go on to spontaneous recovery, and often benefited by faradic stimulation. (3) Menopausal, which may respond to hormone therapy. (4) The commonly met with stress or orthostatic incontinence, usually coming on some years after childbirth, and commonly associated with vaginal laxity.

My interest in the subject dates back more than ten years, when I first met a group of young girls suffering from a congenital form of urinary incontinence not due to any apparent neuropathy. For obvious reasons vaginal intervention was to be avoided, and I searched the relevant surgical literature without getting much help. Cysto-urethroscopic investigation of these cases revealed in all a patulous bladder neck, and I evolved and practised the intravesical tautening operation, which I described to the Section of Urology in January 1939 (*Proc. R. Soc. Med.*, **32**, 777). This entailed a generous excision of the posterior lip of the bladder neck, with a wedge running into the upper urethra. The cut edges of urethra and bladder neck were then approximated snugly around a No. 4 catheter, which was then removed, and suprapubic drainage maintained for ten days.

The results in these congenital cases were so gratifying that when confronted with a multipara who had undergone three vaginal interventions without cure of her stress incontinence, I applied this intravesical operation combined with a Goebell sling of ribbon catgut with complete cure. I operated upon more than a score of such cases by this technique with satisfactory results on the whole. Here is an illustrative case: Mrs. C., aged 38, still suffering from marked stress incontinence, almost complete, despite a colporrhaphy. Intravesical operation with immediate complete cure. Two years post-operatively she developed a severe attack of whooping-cough, and, despite this, there was no incontinence. Now five years post-operatively she remains a complete cure.

a very weak abdominal wall following several laparotomies. I hesitated to advise a sling, but was rather pushed into it. During the operation the catheter escaped from the urethra, and I asked an attendant nurse to reintroduce it. The slings were duly passed round the tube containing the catheter, but at the end of the operation it was found that the catheter was no longer in the bladder but in the vagina. As bad luck would have it the vagina was grossly infected, with the result that infection travelled along the slings which had penetrated the vagina and presumably sloughed. She left hospital as bad as ever. Six months later I heard from her doctor that she was completely cured. Presumably the fibrosis had fixed the bladder neck in the elevated position. It is interesting to note in this connexion that Studdiford has reported that the best results after the Aldridge procedure are noted only nine months later. The reason is not apparent. With my sling I have not found this, and expect an immediate cure of the incontinence.

Operative difficulties.—These are two in number: First, bleeding. From time to time the deep dorsal vein of the clitoris is torn in freeing the upper urethra, and troublesome bleeding can occur. This is best taken care of by means of the coagulating current. I have experienced it only rarely. Secondly, the difficulty in freeing the urethra from the underlying vagina. If too forcible or meticulous freeing is indulged in, the urethra or bladder may be torn, thus leading to suprapubic leakage after the catheter is withdrawn. This will necessitate the reintroduction of the catheter. Since employing the special forceps for tunnelling this accident has not occurred.

Post-operative difficulties.—(*a*) *Urinary leakage*: This I have already mentioned.

(*b*) *Retention* on withdrawal of the catheter. If the patient has not passed urine four hours after removal of the catheter it should be reintroduced. In two cases in which the bladder was allowed to become unduly distended the abdominal wall was on guard, the slings correspondingly tightened, and catheterization was exceedingly difficult, and, in one case, impossible, necessitating a temporary cystostomy. Should this contingency occur it would appear preferable to puncture the bladder by needle suprapubically to relax the structures and then reintroduce the catheter *per urethram*.

(*c*) *Late urinary difficulty*: Two cases have been seen with this complaint, which rapidly responded to a dilatation of the bladder neck.

(*d*) *Basal cystitis*: From time to time a urinary infection will follow as may always occur where urethral instrumentation is necessary, and prove troublesome. Sulphanilamides are administered routinely during the five days the catheter is in situ as a prophylactic.

To sum up, I feel that the congenital type of case, excluding neuropathies, should be treated by intravesical sphincteric tautening along the lines I laid down in 1939. In the acquired cases, and these constitute the vast majority, a properly conducted colporrhaphy and urethroplasty will secure a high proportion of successes. There remains, however, a not insignificant group, where either vaginal intervention by a competent operator has failed, or where no cystocele or urethrocele exists. In these I put in a plea for my sling procedure, which I feel is based on sounder principles than any other yet devised. The psychological trauma of repeated failed vaginal interventions for this distressing form of urinary leakage is immense, and there are few more grateful patients than those cured by a sling after 3, 4, or 5 failed colporrhaphies.

Professor J. Chassar Moir: In May 1944, at a combined meeting of the Sections of Urology and of Obstetrics and Gynæcology, the subject of bladder dysfunction following childbirth was discussed (*Proc. R. Soc. Med.*, 38, 653). I then had the privilege of presenting the case for the "fascial-sling" operation, and of showing a

(3) The third group comprises the suspension operations from above. Mechanically it is always sounder to pull than to push. The Goebell procedure was the prototype, and I have given my reasons for not liking this operation. Many have found it difficult to isolate the bladder neck by the superior approach, and some, like Michon in Paris, use a combined approach, i.e. free the bladder neck from below and then pass the Goebell sling from above. This I have found neither necessary nor desirable. The Aldridge technique is another combined operation now popular, but takes over an hour to perform with all the disadvantages of change in position of the patient, double set of instruments, and change of gown and gloves. I dislike the passing of forceps from the vagina into the retropubic fatty spaces. The modifications of the Goebell operation by Thompson and Miller, wherein the slings are passed anterior to the pubis, merely elevate the lower urethra and so are unsound.

The sling operation I have devised may be thus briefly described:—An 18 Ch. self-retaining catheter is introduced, the bladder emptied and catheter drawn down so that the expanded head is in close proximity to the bladder neck. The vagina is then lightly packed. Transverse abdominal incision, three fingerbreadths above the pubis, is deepened through the skin and subcutaneous tissues, the flaps being undermined. The aponeurosis is now incised in the line of the skin incision, and two straps, each one centimetre wide, are cut from the lower aponeurotic leaf. It should be noted that the pedicles in these straps are muscular. The recti are now separated in the mid-line, and the retropubic space opened up by means of a self-retaining retractor. The bladder neck and urethra are readily identified, thanks to the indwelling catheter. My specially devised curved forceps is then passed below the urethra. Opening the blades enlarges this sub-urethral tunnel, and permits the passage of the aponeurotic straps after being threaded through the outer borders of the recti. The straps are drawn taut and sutured to each other by means of nylon. The space is dusted with sulphanilamide powder, and drained by means of corrugated rubber introduced through a stab incision immediately above the pubis. Aponeurosis and skin are closed. The catheter is retained for five days.

In what type of case do I advocate this operation? Not in every case of stress incontinence, to be sure, for those associated with a definite cystocele or combined cystocele and rectocele, should certainly be operated upon from below, and cure will be obtained in 50% to 80% of cases according to the skill of the operator. Though this may occasion some surprise, these are published figures and correspond with what my own researches have shown. Many apparent cures seem to relapse twelve to eighteen months later due to stretching of the sutured fasciæ. The fact that so many different operations have been designed to remedy the condition shows that the vaginal interventions fall short of a 100% cure ratio. Where a properly conducted vaginal repair has failed to cure the incontinence then I believe that my sling procedure should be employed. In the group of cases where no cystocele is present, and in the nulliparous, I advise a sling in the first instance. Bonney's test of supporting the bladder neck on either side with a finger *per vaginam* and requesting the patient to cough demonstrating that loss of urine will not occur under these conditions, supports my contention that all that is required to cure the condition is permanent elevation of the bladder neck, and that plication of the sphincter or urethra is quite unnecessary.

Results.—I have now performed the operation 67 times. I have records of only one case which relapsed. This woman had had two previous colporrhaphies and a failed intravesical tautening. She left the hospital apparently cured, but when seen five months later was again incontinent. There is one particularly interesting case who had a severe degree of incontinence following a colporrhaphy. She had

We must now decide which method is easiest, safest and surest. In my opinion, the Aldridge operation is easiest, and it also avoids a disadvantage inherent in both the Studdiford and Millin operations of a wide opening up of the space of Retzius. In the Millin operation, there also seems to be a distinct hazard of penetrating into the vagina, or of damaging the urethra or neck of the bladder in passing the dissecting instrument down from above. On the other hand, it avoids the complication of a combined abdominal and vaginal dissection. The risk of infection (never very great) is also presumably lessened.

In the technique of the Aldridge operation the only step in the dissection presenting difficulty is the starting of the "tunnels". The colporrhaphy dissection should be carried slightly further than usual to the sides of the upper urethra. The operator then locates the descending ramus of the pubis with his finger, and by a little sharp dissection gains access to the structures at the inner margin of that bone, an inch, or a little more, below and lateral to the under-margin of the symphyseal joint. At that point, a firm layer of fibrous tissue will be felt preventing access to the space of Retzius. With blunt-pointed, curved scissors, firm pressure is put on the tissues at the edge of the bone (avoiding periosteum), and by making a few snips a passage is broken open which can then be enlarged with the point of the finger. It is now an easy matter to pass the finger up behind the pubic bone to meet the abdominal dissection.

A second difficulty is to judge the correct tension to put on the fascial strips when they are united. I draw the strips down fairly firmly and make them cross under the urethra. At this point a fine nylon suture is inserted. A catheter is now introduced into the urethra; if it can be pushed into the bladder fairly easily, but at the same time can be felt to negotiate a decided "bump" or "ridge" at the level of the sling, all is well, and two or three further nylon stitches are then inserted to secure the fascial strips. If, however, matters are not as described, the first nylon stitch is removed and the necessary adjustments made. Finally, instead of cutting off the redundant ends of the strips, they are made to cross over, and are anchored by further sutures to the tissues at the sides of the bladder.

Catheter drainage is maintained for ten days during which time the patient is given sulphanilamide, 0·5 gramme, four-hourly. The catheter should be inserted so that its "eye" is 3 in. distant from the external urethral meatus, and it should be anchored by a firm stitch to the tissues of the anterior lip of the urethral meatus.

Finally, I should like to refer to the use of the sling operation in patients who have had a vesico-vaginal fistula repaired, but who, because of extensive destruction of the sphincteric region of the bladder, are still incontinent of urine. In a series of some 36 cases of vesico-vaginal fistula successfully closed by vaginal operation, I have had 7 in which a seemingly perfect result has been marred by a slight or severe degree of urinary incontinence. (2 of these were cases in which the entire urethra had been destroyed, and in whom a new urethra had been fashioned by the Gray Ward technique.) By use of the fascial sling, 2 patients have been completely cured, and 2 others have been very greatly relieved. In one further case (a urethral reconstruction) the operation was unnecessary for great relief was obtained by use of a Hodge pessary, inserted in such a way that the rounded end pressed forward on the urethra. This patient learned to insert the ring herself each morning; and from being completely "house-bound", she has become able to earn her living as a secretary and has recently re-married. The two remaining patients are still awaiting treatment by the sling operation.

patient who had been successfully treated by this method for stress incontinence of urine that had persisted after the closure of an extensive vesico-vaginal fistula.

In my opinion the fascial sling operation should be strictly reserved for the case in which the simpler and safer procedure of colporrhaphy, together with a tightening of the tissues below the bladder neck, has been tried and has been found unsuccessful. It has been stated to-night that the failures following the orthodox colporrhaphy amount to not less than 40% of cases. This is contrary to the experience of most gynæcologists (*see* Stallorthy, J., *J. Obstet. Gynæc.*, 1940, **47**, 391), and I cannot allow so pessimistic a statement to pass unchallenged. If the operation is adequately performed the failure rate should be very much less, although I agree that it is far from negligible.

In 1929 I saw Werner of Vienna perform the Goebell-Stoeckel operation. Two narrow ribbons of fascia were dissected down from the anterior abdominal wall and left attached to the pyramidalis muscles. With the patient in the lithotomy position, exposure of the urethra and bladder neck was then made as in the orthodox colporrhaphy operation, and a tunnel opened up into the space of Retzius on both sides. The fascial bands were now pulled down by means of long forceps and were united under the neck of the bladder.

In 1942, Aldridge described a modified technique in which strips of fascia were dissected from the abdominal wall, above, and parallel to, the inguinal ligaments. These strips were left attached to the recti muscles about one inch above the pubis. The remainder of the operation was as already described, save that the vaginal repair included an infolding and tightening of bladder fascia as is usual in a colporrhaphy.

Later, Studdiford advocated another modification. After making the tunnels at the sides of the upper urethra, he completed the colporrhaphy and closed the vaginal incision. He then dissected down a single, long, vertical strip of fascia from the front of the recti muscles leaving the base attached about 1 in. above the pubis. This strip was then mounted on an aneurysm needle and pushed down through one of the previously dissected tunnels, round the upper urethra, then up through the other tunnel, to be attached to the fascia of the opposite rectus muscle. Thus, a single sling of fascia extended from the lower end of one rectus muscle to the lower end of the other. This technique differed from that of the Goebell-Stoeckel operation in eliminating the need for joining two fascial strips under the urethra.

My assistants, Mr. Scott Russell and Mr. G. G. Lennon, and myself have tried both the Aldridge and Studdiford techniques with success. The first operation has the merit of simplicity and is, on the whole, the one I favour. The second requires a wide separation of the recti muscles and a considerable pushing down of the bladder from the inner side of the symphysis pubis (i.e. opening up the space of Retzius) in order to give sufficient access to the upper urethra. And there are other disadvantages. In dissecting up the fascial strip a good deal of trouble is experienced from numerous bleeding points; and when the strip is finally obtained, it will be found that there are weak spots corresponding to the tendinous intersections which are liable to tear if more than a moderate pull is exerted.

It may be worth mentioning that in one of my cases there had been so many previous abdominal operations that it was impossible to find a clear space on the abdominal wall from which to dissect up a fascial strip. I therefore obtained a fascial strip from the thigh and inserted it to form a sling after the manner of the Studdiford operation. An excellent result was obtained.

I have not had any experience of the new and very successful Millin operation, but it seems to me that the various sling operations all achieve the same end-result.

We know that a badly conducted third stage of labour can cause post-partum hæmorrhage, the bad conduct consisting usually of feeble attempts to express the placenta by massaging it and pushing the uterus downwards. This downward pressure of the uterus I consider a dangerous thing; possibly it causes uterine engorgement by hindering the flow of blood in the uterine veins, and if the uterus is to be touched at all, I consider it should be held with a wide grip suprapubically, and, if anything, pushed upwards rather than downwards.

Supposing that hæmorrhage now occurs, attempts at Credé's expression are made, but fail. There is no advice we can give the midwife except the manual removal of the placenta, which, in a primigravida, I doubt if a midwife could do on her own, the patient being given no anæsthetic. Even if the midwife could perform this operation, it would be extremely dangerous by causing shock in the already exsanguinated patient.

Under these circumstances the midwife is discouraged from using any oxytocic drug, chiefly on account of the danger of the formation of a constricting ring. If this danger were not present, the drug might well make the attempted manual removal unnecessary.

About 1935, in the Obstetric Unit of University College Hospital, thanks to Professor F. J. Browne, 0·5 mg. ergometrine was given intramuscularly to 500 consecutive normal cases, as soon as the head was delivered. In no case was there any evidence of a constricting ring, and in no case was manual removal necessary, nor was there any other catastrophe such as acute inversion of the uterus. Mr. Peel tells me that a similar experiment has been carried out at King's College Hospital, using 5 units of pituitary extract. In this much smaller series of cases, I believe about 100, a constricting ring occurred twice. It would seem therefore that this danger is very real with the use of pituitary, but I have yet to see cases or hear of this occurrence attributable to ergometrine.

I am not suggesting that we should teach the routine use of ergometrine during the third stage. Personally, in cases of third stage hæmorrhage I have no hesitation in giving 0·25 mg. intravenously, but I do suggest that we should advise the intramuscular injection of ergometrine before manual removal is attempted. Having removed the placenta, it is universally agreed that oxytocic drugs may be used, and at this point I would like publicly to deprecate the impertinence of some local supervising authorities who forbid their midwives to carry any oxytocic drugs.

By this action they remove a powerful weapon from the midwife's armament, placing the life of every patient in their area in unnecessary and unjustifiable danger. Which of us would like to attend a confinement without having some oxytocic drug available?

The placenta removed, severe bleeding is now best controlled by bi-manual compression. Again, a difficult and somewhat dangerous procedure in the unanæsthetized patient. How many of you have tried this manœuvre with both hands on the abdomen?

A broad suprapubic grip on the uterus is maintained and the other hand placed on the posterior wall of the uterus *per abdomen*. Unless the patient be grossly fat, it is surprising to find how efficiently the placental sinuses can be compressed by this method.

Professor Hilda N. Lloyd: *General remarks.*—Management of the third stage of labour in normal cases is the management of the whole labour—the first and second stages having managed themselves. It is the one stage where interference and meddlesome midwifery can do more harm than at any other time. It is important to know and to teach students and nurses what is happening during the third stage of labour.

Mr. D. M. Stern said that he thought the attitude to the treatment of stress incontinence was too symptomatic.

There was more than one cause for this condition, and only a careful study of each patient, and a knowledge of a normal physiology and anatomy of micturition would enable one to make an accurate diagnosis before attempting a cure. This was confirmed by the varied success met with in the different operative procedures.

The causes can be grouped under five headings: (1) Cystocele. (2) Prolapse of the urethra. (3) Damage to the internal sphincter. (4) Rupture of Bell's muscle. (5) Extrapelvic causes, such as spina bifida and neurological lesions.

In a series of 77 cases, 60 were due to cystocele with, or without, urethral prolapse, 11 to urethral prolapse only, 2 to rupture of Bell's muscle, 2 to damage to the internal sphincter, and 2 to extrapelvic causes.

Fixation of the urethra by the vaginal approach cured those cases due to urethral prolapse. There are only two failures in the whole series, and both of these were complicated by fistula with extensive loss of tissue, due to trauma and infection.

[*January* 17, 1947]

DISCUSSION ON THE MANAGEMENT OF THE NORMAL THIRD STAGE OF LABOUR AND OF HÆMORRHAGE THEREIN

Mr. J. D. S. Flew: In the majority of textbooks the advice given concerning the third stage is stereotyped. The patient is turned on to her back, a hand is placed on the abdomen, signs of placental separation must then be awaited, after which the placenta is expressed and then, if necessary, oxytocic drugs may be given. Should excessive bleeding occur, the placenta must be removed either by Credé's method or by manual removal, after which the bleeding is controlled by oxytocic drugs, possibly a hot intra-uterine douche, and—if these methods fail—bi-manual compression.

Little or no research has recently been published on the mechanics of the third stage of labour. It is believed that placental separation is initiated by uterine retraction, but this alone is insufficient.

Barbour in 1899 showed that the placental site could be diminished from approximately 38 sq. in. down to 14 sq. in., as a result of which no placental separation occurred. This was demonstrated in the case of a uterus removed by Porro's operation, and no retroplacental hæmatoma was present.

This is the second factor which normally causes placental separation, the third being the pressure of the uterine walls bearing down on the placenta.

It is customary to teach that the signs of placental separation are the rising of the fundus, the gush of blood *per vaginam*, and the permanent lengthening of the cord. These of course are signs of placental descent rather than actual separation, the separation having occurred beforehand.

If uterine retraction initiates placental separation, then surely this will commence at the time of maximum retraction, namely at the moment of the birth of the child's body, and we then wait for the secondary factors to complete the process.

I am not so much concerned as to how you and I conduct the third stage of labour, or deal with cases of excessive hæmorrhage; doubtless we express the placenta at once, and possibly at times aid this process by traction on the cord. Rather I am concerned here with what we teach our students and, in particular, our pupil midwives, on how to conduct the third stage of labour and the management of excessive hæmorrhage. Once qualified, the midwives conduct 60% of the midwifery of this country without a medical practitioner being present, and I doubt if the routine advice given to them is the best for the patient.

In those cases requiring methedrine this response usually takes place and is almost always permanent.

Fluid (water) by mouth is encouraged.

The patient is then anæsthetized with pentothal after full cleansing and catheterization. Usual amount required 0·25 gramme. If placenta still in uterus (most cases) manual removal carried out without any attempt at expression.

Amyl nitrate given for cases with contraction ring—not always effective when severe probably because of light anæsthesia.

Ergometrine 0·125 mg. given i.v. as placenta is removed. (Hot douche is rarely necessary in these cases and usually no further hæmorrhage is encountered.) This is chiefly due to the lightness of the anæsthesia.

Perineum examined and perineorrhaphy performed if required.

Blood.—Total amount given: In some cases 2 pints at least sometimes 3 pints. All Group 0 Rh negative. No cross matching performed. The blood testing is reliable and this is not necessary.

Follow-up. On fifth day full blood-count carried out by Blood Transfusion Service. If hæmoglobin is below 50% (rarely) then further blood transfusion is given. (Plasma not given if avoidable now in view of risk of homologous serum jaundice.)

Dr. Peter Denham, *Assistant Master, Rotunda Hospital, Dublin*: Fundal control during the third stage, practised in the Rotunda from 1786 and before, and known as the Dublin method, has been abandoned at the Rotunda for almost twenty years. The normal third stage is now conducted without any such control.

Routine of normal third stage, after spontaneous delivery, uncomplicated breech or low forceps, not involving any long or deep anæsthesia and after a labour not unduly prolonged: The patient is delivered in the left lateral position or turned back into it after delivery and remains in that position during the third stage. Her condition is noted now and observed all through by the labour ward Sister. After the cord has been divided and dressed the student midwife returns to the couch to observe the patient's condition and ready to swab down the vulva and perineum using a sponge holder. When the cord lengthens and a gush of blood indicates the separation and expulsion of the placenta into the vagina the Sister may feel the fundus and note the other signs of separation and expulsion. Then a catheter is passed and the uterus is rubbed up and gentle and intermittent pressure on the fundus expels the placenta and membranes intact from the vagina. After this the uterus is rubbed up every five minutes for the next half-hour and at frequent intervals for the next three hours.

This routine is modified in certain cases: (1) History of previous post-partum hæmorrhage. (2) Operative deliveries that may be associated with damage. (3) After prolonged labours and deep anæsthesia. (4) Cases of ante-partum hæmorrhage.

(1) *Prophylaxis* for those patients who have had a P.P.H. on a previous pregnancy: They are given extra calcium, in the form of osteocalcium two tablets t.i.d., vitamin K one tablet b.d., for the last three weeks of pregnancy. They are admitted at 38 weeks and given 2½ grains of quinine daily. That is all, until at delivery we administer 5 units of pituitrin when the head is crowned, and control the fundus in order to be ready for manual removal.

(2) After a difficult and traumatizing delivery, e.g. craniotomy or difficult version, we do not hesitate to perform an immediate manual removal to secure these advantages: (*a*) Rupture may be diagnosed or excluded, e.g. after a difficult internal version. (*b*) We are then in a strong position in regard to the administration of oxytocics. (*c*) The placenta is not going to come down over an incompletely

repaired perineum. (*d*) Later interference will not be necessary, and no second anæsthetic will be required.

(3) Similarly, after a very long labour, e.g. inertia, immediate manual removal is indicated.

(4) The danger of this period to cases of ante-partum hæmorrhage is hardly sufficiently stressed. The accidental hæmorrhage usually presents no difficulty, the placenta coming away immediately but even the minimum of loss may be enough to turn the scales. The danger in cases of placenta prævia is greatly increased as, the placental site being in the non-retractive part of the uterus, there is not the same control of P.P.H. These cases must be given oxytocics and the fundus well and continuously controlled if disaster is to be avoided. I would like to mention that over the last twenty years almost one-half of those who died of placenta prævia died of P.P.H.

The *abnormalities* that arise at this period are chiefly four: (1) Hæmorrhage before delivery of the placenta. (2) Hæmorrhage after delivery of the placenta. (3) Retention of the placenta without hæmorrhage. (4) Obstetric shock.

I am deliberately excluding cases of traumatic P.P.H., as they are only due to lack of skill on the part of the attendant, also cases delivered abdominally are in a category of their own.

(1) If hæmorrhage is noted without the signs of placental separation we pass a catheter, rub up the fundus, and make an effort to express the placenta by Credé's method gently. If this fails the patient is anæsthetized and the manœuvre is again attempted once. Manual removal is then resorted to without further delay.

We feel strongly that if Credé's method is persisted in it may become a brutal and shocking procedure and that with chemotherapy at even its present level manual removal is not an operation to be feared.

The technique of manual removal needs no description except to say that the hand is always introduced a second time to make sure that no cotyledon has been left behind; and to perform a bi-manual massage. Oxytocics are now given. The uterus always responds to this routine but if it did not plugging would now be resorted to. (This has only been done once in the three years in a case of placenta prævia. In another case, a woman was brought in moribund from hæmorrhage, the placenta had already been delivered and she died ten minutes after admission while being plugged.)

(2) After delivery of the placenta we have always been able to control any hæmorrhage by rubbing up the uterus abdominally and administering oxytocics, except in one case who had a rupture of the vaginal vault and uterus during a spontaneous delivery.

(3) Retention of the placenta. In the absence of hæmorrhage we leave the uterus alone for half an hour, unless there is indication that the placenta has separated or that something is wrong. At the end of that time a catheter is passed, a hand is placed on the abdomen. This often reveals that the placenta is lying in the vagina (where it may well have been for the past twenty minutes if the attendant has not been observant). During this time the operator is quietly observed by Sister to make sure that he is not yielding to temptation and becoming *fundus fiddler*.

If the placenta is still *in utero* no cause for alarm is felt. The trolley is prepared for a manual removal and a further period of half an hour is allowed to elapse during which the fundus may be palpated twice, as before, to see that the placenta has not come away in the meantime and that the uterus has not filled up with blood. . . . At the end of this time an attack may be made on the patient by Credé's method. I deliberately say "attack"; this shocking manœuvre often only partly separates the placenta and causes bleeding to start. It is never to be attempted without adequate resuscitation measures being ready and waiting. If the first effort is not crowned with success we may try again under anæthesia and then go on to manual removal. Thus we take half an hour to be the normal duration of the third stage, but do not consider anything less than an hour to warrant interference, in the absence of hæmorrhage. The injection of saline along the cord is occasionally done, but it only acts in my opinion by giving Nature a little more time to act, and it is only used as a demonstration for teaching purposes. In the presence of hæmorrhage it is an unjustified waste of time.

(4) Obstetric shock, that is to say unexpected shock coming on an hour or so more after the completion of the third stage, is a condition I have not met. I have seen patients collapse and even die two hours after delivery, particularly bad cases of toxæmic accidental hæmorrhage who responded well to the earlier treatment at the time of delivery, and appeared out of danger only to collapse in this way some two hours later. I have always considered this to be due to neglect on my part in that the restorative measures have been abandoned too early and this secondary shock (Moon) had developed. Also absorption of toxæmic elements from the apoplexy in the uterine muscle has probably a bearing on the causation. The cases reported from time to time are usually due to unrecognized loss, possibly in a patient already anæmic. That there is a special type of shock unassociated with trauma or hæmorrhage made for the scourge solely of obstetricians I am very loath to believe.

The results achieved are as follows:

Vaginal deliveries	*Manual removal*	%	
7,284	69	0·95	Rotunda
6,086	77	1·2	Glasgow
2,685	43	1·6	Edinburgh

Stander in William's "Obstetrics" claims 0·2% but the report of the New York Lying-in Hospital (1939) shows almost three times this with an incidence of inversion of the uterus of 1/4,000, a condition that has not been seen in the Rotunda for at least twenty years.

Mr. G. F. Gibberd: In the management of the third stage of labour, three issues only were discussed, because they were probably the most debatable. Reasons were given for taking the following views: (*a*) That throughout the third stage of labour the hand should "guard" the fundus of the uterus more or less continuously; (*b*) that oxytocic drugs should never, in any circumstances, be given before the delivery of the placenta; (*c*) that, provided that the patient is in suitable surroundings, delay of two hours in the third stage of labour is a proper indication for expression of the placenta by Credé's method.

Mr. Gibberd then continued: For the management of hæmorrhage in the third stage of labour in the practice of a midwife acting alone, the routine treatment should not exceed two attempts at expression of the placenta. No one seriously expected a midwife to embark upon the operation of manual removal of the placenta or of bi-manual compression of the uterus without an anæsthetic. There was every reason to believe that such heroic treatment if adopted was more likely to kill the patient than to save her life. It was therefore important to cease advocating a treatment simply for traditional reasons, and more emphasis should be placed upon the importance of the general measures for combating collapse that can be applied while proper assistance is awaited.

There were three reasons, two common, and one extremely rare, for failing to express the placenta by Credé's method. The common reasons were (*a*) Mechanical difficulty in securing a satisfactory grip of the uterus (e.g. an obese abdomen); and (*b*) a contraction ring. The rare reason—the speaker himself had not met a case—was a "total" placenta accreta. Cases of "focal" placenta accreta, though not so excessively rare, did not present themselves clinically as cases of "retained placenta", but rather as cases of retained fragments of placenta. If two attempts at Credé's expression fail, the difficulty under (*a*) will not be lessened, and the difficulty under (*b*) will be increased by further attempts. However urgent the hæmorrhage may be, no other local treatment should be attempted until an anæsthetist is available and proper preparations have been made for manual exploration of the uterus. One more attempt at expression under anæsthesia should be made. If the difficulty was inaccessibility of the uterus, the anæsthesia is generally sufficient to overcome the difficulty. If the attempt at expression under anæsthesia fails, manual removal of the placenta should be embarked upon immediately. With the exception of "total" placenta accreta and of certain very rare examples of angular pregnancy, there is only one cause of mechanical difficulty in manual removal of the placenta, viz. a contraction ring. This contraction ring may, rarely, be so marked as entirely to defeat attempts at removal of the placenta. More often it causes varying degrees of difficulty on account of its cramping action on the fingers of the hand which is trying to detach the placenta. When one has, with the greatest difficulty, detached and removed a placenta, it is very easy to mistake inaccessibility for so-called "morbid adhesion". I believe "morbid adhesion" is always a mistaken diagnosis. The placenta may be very difficult to remove, but the difficulty arises, not from undue adherence of the placenta, but from the mechanical disadvantage under which a contraction ring forces anxious fingers to work. I recognize (though I have never personally met) a condition of "total" placenta accreta. There is the physiological condition of "normal adhesion" of the placenta. I am not satisfied that there is any anatomical basis, or any sufficient clinical evidence, for postulating any intermediate condition between these two extremes.

The Treatment of Tuberculous Salpingitis with Special Reference to X-ray Therapy

By Elliot Philipp, M.R.C.S., L.R.C.P.

It has been suggested to me that it might be of interest to present the results of treatment of tuberculosis of the female genital tract as carried out at the Middlesex Hospital in the past few years.

The diagnosis is not always easy, but there are said to be certain features in tuberculous salpingitis which may help one to arrive at the correct answer. The age-incidence is usually acknowledged to be between 15 and 35 years although it may occur at any age. In this series the youngest patient was 14½ years old and the oldest 36 when the condition was first diagnosed. The patient is said often to be a virgin, but 8 of this series of 20 cases were married. There may or may not be signs and symptoms usually associated with tuberculosis, such as night-sweats, loss of weight and evening rise of temperature. Amenorrhœa is sometimes present but menorrhagia is more often a symptom of the condition.

Usually the diagnosis can only be made with certainty at laparotomy: even then it is not always easy and sometimes the pathologist's report from a section of tube, omentum or other tissue removed is the first indication of the true nature of the condition.

In only one of these cases was the diagnosis made from the examination of curettings without laparotomy. This is the ideal means of diagnosis avoiding as it does laparotomy, which may light up the condition and even give rise, as in one case, to fatal issue. Of these 20 cases 13 were treated with X-rays, 7 by surgery alone. 5 of those treated by operation only were comparatively healthy women. One was treated with streptomycin and sanatorium treatment and the seventh died before X-ray therapy could be commenced. She was a girl of 23 who had complained of a swelling in the lower abdomen which had been diagnosed as an ovarian cyst and she was operated on in October 1946. On opening the abdomen a large matted mass was found and it was impossible to distinguish tubes from gut. Multiple tubercles were present. Nothing was done in the way of attempting to remove any diseased organ. The abdomen was closed and the wound appeared to be well healed after ten days. After four weeks, however, a fæcal fistula developed. The patient went downhill rapidly and died within two months.

As far as I could ascertain none of the cases treated with X-rays has relapsed and none died. But one could not be traced again after her first course of treatment and another attended follow-up for three years but has not been seen since 1944.

The X-ray treatment involves giving very small doses—a total of about 600 r in a course of twelve to eighteen treatments spread over six to nine weeks. That is, as a general working rule, two treatments a week. The dosage is small. The total is about a quarter or a third of the menopausal dose. A course may be repeated after an interval of a few months without the production of a menopause; and if there is a sinus a small dose can be given to the skin which often helps to close the sinus.

Of the 13 cases treated with X-rays 12 had had a laparotomy; 4 of these had developed a tubercular sinus, and 1 who had had hysterectomy and bilateral salpingo-oophorectomy for the condition developed a foul discharge from the cervical stump; this discharge contained tubercle bacilli. Within six months of the start of X-ray treatment all the sinuses had healed.

Periods were regular at a recent follow-up in 5 cases.

One had acquired an X-ray menopause which is unusual and undesirable; 2 had had hysterectomy, one was aged 45, another was having scanty irregular periods, and about 3 information is vague. No case had continuance of menorrhagia which is one of the commonest presenting symptoms in this series.

The case which was diagnosed on curettage only is of particular interest. In 1941 she was complaining of profuse menorrhagia. She had had tuberculous glands in her neck and a big swelling could be felt abdominally. Her temperature rose to 103°F. Histological examination of the endometrium revealed many tubercles. She received two courses of X-rays and is to-day completely symptom-free. The abdominal tumour has disappeared and she is having normal periods.

Of the cases that did not receive X-rays one had what was obviously a very chronic infection. The diagnosis was not suspected even at laparotomy and just by chance a piece of fallopian tube removed and sectioned revealed tuberculous salpingitis. She has done well.

One had pan-hysterectomy for the condition and is well.

Another who had bilateral salpingectomy and left oophorectomy for the condition complains only of dysmenorrhœa. She had two sinuses which took fifteen months to heal.

One, as recounted, died. The fifth case had bilateral salpingectomy. She is well now. Another case had an old chronic infection discovered when myomectomy was being carried out for menorrhagia. Menorrhagia has ceased.

There were three reasons, two common, and one extremely rare, for failing to express the placenta by Credé's method. The common reasons were (*a*) Mechanical difficulty in securing a satisfactory grip of the uterus (e.g. an obese abdomen); and (*b*) a contraction ring. The rare reason—the speaker himself had not met a case—was a "total" placenta accreta. Cases of "focal" placenta accreta, though not so excessively rare, did not present themselves clinically as cases of "retained placenta", but rather as cases of retained fragments of placenta. If two attempts at Credé's expression fail, the difficulty under (*a*) will not be lessened, and the difficulty under (*b*) will be increased by further attempts. However urgent the hæmorrhage may be, no other local treatment should be attempted until an anæsthetist is available and proper preparations have been made for manual exploration of the uterus. One more attempt at expression under anæsthesia should be made. If the difficulty was inaccessibility of the uterus, the anæsthesia is generally sufficient to overcome the difficulty. The Treatment of Tuberculous Salpingitis with Special Reference to X-ray Therapy

By Elliot Philipp, M.R.C.S., L.R.C.P.

It has been suggested to me that it might be of interest to present the results of treatment of tuberculosis of the female genital tract as carried out at the Middlesex Hospital in the past few years.

The diagnosis is not always easy, but there are said to be certain features in tuberculous salpingitis which may help one to arrive at the correct answer. The age-incidence is usually acknowledged to be between 15 and 35 years although it may occur at any age. In this series the youngest patient was 14½ years old and the oldest 36 when the condition was first diagnosed. The patient is said often to be a virgin, but 8 of this series of 20 cases were married. There may or may not be signs and symptoms usually associated with tuberculosis, such as night-sweats, loss of weight and evening rise of temperature. Amenorrhœa is sometimes present but menorrhagia is more often a symptom of the condition.

Usually the diagnosis can only be made with certainty at laparotomy: even then it is not always easy and sometimes the pathologist's report from a section of tube, omentum or other tissue removed is the first indication of the true nature of the condition.

In only one of these cases was the diagnosis made from the examination of curettings without laparotomy. This is the ideal means of diagnosis avoiding as it does laparotomy, which may light up the condition and even give rise, as in one case, to fatal issue. Of these 20 cases 13 were treated with X-rays, 7 by surgery alone. 5 of those treated by operation only were comparatively healthy women. One was treated with streptomycin and sanatorium treatment and the seventh died before X-ray therapy could be commenced. She was a girl of 23 who had complained of a swelling in the lower abdomen which had been diagnosed as an ovarian cyst and she was operated on in October 1946. On opening the abdomen a large matted mass was found and it was impossible to distinguish tubes from gut. Multiple tubercles were present. Nothing was done in the way of attempting to remove any diseased organ. The abdomen was closed and the wound appeared to be well healed after ten days. After four weeks, however, a fæcal fistula developed. The patient went downhill rapidly and died within two months.

As far as I could ascertain none of the cases treated with X-rays has relapsed and none died. But one could not be traced again after her first course of treatment and another attended follow-up for three years but has not been seen since 1944.

The X-ray treatment involves giving very small doses—a total of about 600 r in a course of twelve to eighteen treatments spread over six to nine weeks. That is, as a general working rule, two treatments a week. The dosage is small. The total is about a quarter or a third of the menopausal dose. A course may be repeated after an interval of a few months without the production of a menopause; and if there is a sinus a small dose can be given to the skin which often helps to close the sinus.

Of the 13 cases treated with X-rays 12 had had a laparotomy; 4 of these had developed a tubercular sinus, and 1 who had had hysterectomy and bilateral salpingo-oophorectomy for the condition developed a foul discharge from the cervical stump; this discharge contained tubercle bacilli. Within six months of the start of X-ray treatment all the sinuses had healed.

Periods were regular at a recent follow-up in 5 cases.

One had acquired an X-ray menopause which is unusual and undesirable; 2 had had hysterectomy, one was aged 45, another was having scanty irregular periods, and about 3 information is vague. No case had continuance of menorrhagia which is one of the commonest presenting symptoms in this series.

The case which was diagnosed on curettage only is of particular interest. In 1941 she was complaining of profuse menorrhagia. She had had tuberculous glands in her neck and a big swelling could be felt abdominally. Her temperature rose to 103°F. Histological examination of the endometrium revealed many tubercles. She received two courses of X-rays and is to-day completely symptom-free. The abdominal tumour has disappeared and she is having normal periods.

Of the cases that did not receive X-rays one had what was obviously a very chronic infection. The diagnosis was not suspected even at laparotomy and just by chance a piece of fallopian tube removed and sectioned revealed tuberculous salpingitis. She has done well.

One had pan-hysterectomy for the condition and is well.

Another who had bilateral salpingectomy and left oophorectomy for the condition complains only of dysmenorrhœa. She had two sinuses which took fifteen months to heal.

One, as recounted, died. The fifth case had bilateral salpingectomy. She is well now. Another case had an old chronic infection discovered when myomectomy was being carried out for menorrhagia. Menorrhagia has ceased.

The girl who had streptomycin has done well in spite of very small dosage. She is at a sanatorium in Switzerland. Her sinus has healed seven months after laparotomy with appendicectomy.

From all these cases the conclusion that can be drawn is that there is, as yet, no fixed rule for treatment of tuberculous tubes.

Rest, good food and heliotherapy all play their part. Though radical surgery is said to be of great value it may equally well be that surgery leads to a breakdown of protective barriers limiting the spread of the disease, to sinus formation and even to fæcal fistula. It does appear that X-ray therapy has a definite place in the condition. How the treatment works may possibly be something like this:

Small doses of X-rays traumatize tissues and destroy the most sensitive cells which are the lymphocytes. There is a general reaction to remove the destroyed cells and a very low-grade aseptic inflammation is set up which helps to overcome the tuberculous infection which previously had not been adequately combated.

I should like to thank Mr. Rivett and Mr. Winterton who operated on several of these cases and who have so kindly allowed me to use their material and also Professor Windeyer and Dr. Japha who have helped in the compilation of this paper.

Full-term Intraligamentary Pregnancy.—I. T. FRASER, F.R.C.S.Ed.

Mrs. McD., aged 26, para 0. One previous miscarriage in 1943. Admitted to University College Hospital, 3.5.46.

Last menstrual period 10.8.45. Commencing one week later, the patient had slight vaginal bleeding, and shortly afterwards experienced pain in the right lower abdomen. At 11 weeks' gestation, two pieces of "membrane" were passed, and thereafter there was a brownish vaginal discharge.

At 13 weeks' gestation the patient was admitted to Watford Peace Memorial Hospital under the care of Professor F. J. Browne. Xenopus test was positive, and she was discharged four weeks later, pregnancy continuing. At 22 weeks' gestation, the fundus was at the level of the umbilicus, but no movements had been felt. Xenopus test was now negative. At 30 weeks' gestation, fœtal heart was not heard, and X-ray examination at Watford showed the fœtus to be lying obliquely in an attitude of extreme flexion. It was thought to be dead. Some brownish discharge continued to leak vaginally. The patient was admitted to University College Hospital at 38 weeks' gestation as a case of missed abortion.

Examination showed the fundus to be 2 in. above the umbilicus. The head was felt to the left side of the fundus but was not ballotable. Fœtal heart was unexpectedly heard, rate being 120. Vaginal examination revealed fœtal limbs, felt very easily in posterior fornix.

X-ray examination showed an oblique lie of the fœtus, with such flexion of the spine that the radiologist was convinced that the fœtus was dead.

The fœtal heart continued to be satisfactorily heard, and there was a slight watery discharge *per vaginam*. A tentative attempt at version without anæsthesia was unsuccessful.

Patient experienced slight lower abdominal pains on 21.5.46, the expected date of delivery. Next day the fœtal heart had ceased. During the course of the next few weeks, two medical inductions were given without success. Further X-ray at 44 weeks' gestation showed marked collapse of the fœtal skull.

Abdominal pregnancy was considered to be a possible diagnosis. The patient was examined under anæsthesia on 2.7.46, at 46 weeks' gestation, fœtal limbs being felt with great ease in the posterior fornix. The fundus uteri could not be distinguished separately from the main swelling. A dilator passed into the uterus for 5 in., further passage not being attempted.

Laparotomy was performed. A left intraligamentary pregnancy was found, the fœtus being contained in a large ovisac, covered with fairly thick membrane and peritoneum. The uterus was enlarged and incorporated in its anterior wall. The left tube extended laterally from the uterine cornu over the sac for 3 in. before ceasing. An extension of the sac to the right contained the placenta. There were no adhesions to omentum or intestines.

The sac was opened and the fœtus removed. It was severely macerated, weighing 4 lb. There was no congenital deformity. The left ovarian ligament was divided, and the sac separated from the back of the uterus by blunt dissection. The attachment of the sac to the left side of uterus was now divided and, separating the base from the pelvis, removal was completed. The raw areas were reperitonized, and the abdomen closed.

The patient made an uninterrupted recovery and was discharged twenty-one days after operation.

Comment.—Intraligamentary pregnancy is rare. Champion and Tessitore in 1937 could find only 70 cases where such pregnancy had proceeded past the 28th week of gestation.

The apparent leakage of liquor, presumed to come from a normal uterus, was partly responsible for the delay in diagnosis. There were, however, many suggestive features—the history of pain, bleeding and of "membrane" being passed; the fixed malpresentation, uncorrectable by version, non-engagement of the presenting part and ease of feeling fœtal parts vaginally.

The attitude of the fœtus, suggesting intra-uterine death before it actually occurred, is of interest.

Had the correct diagnosis been made earlier, laparotomy before term might have resulted in a living fœtus. The high incidence of congenital abnormality in fœtuses resulting from ectopic pregnancy, noted by Von Winckel, necessitates the use of radiography to exclude this possibility, before laparotomy is carried out.

In abdominal pregnancy, which is indistinguishable from intraligamentary pregnancy before laparotomy, De Lee (1943) recommends laparotomy six weeks after term, as separation of placental adhesions to bowel may result in severe hæmorrhage in cases dealt with prior to fœtal death. However, the modern practice of leaving the placenta in situ when it is adherent to viscera has improved the results of the early operation.

Uterine Rupture.—IAN DONALD, M.B.

A case of uterine rupture following a previous classical Cæsarean section is not in itself remarkable but this case presented certain rather interesting features; first the rupture occurred at the end of the very last pain with which the head was born and this in the second place produced an unusual and confusing third stage, as might be expected, and thirdly a manual removal of the placenta was unwittingly carried out without the large rent in the uterus being discovered.

The patient is a healthy woman of 38 who, three years previously, at the age of 35 had a classical Cæsarean section for a breech with extended legs, her somewhat elderly primiparity being an additional indication. It is known for a fact that the uterus was sutured with interrupted catgut.

In this pregnancy the vertex presented and as there was no disproportion it was decided to allow her to proceed to natural delivery. This she achieved in 25 hours

The girl who had streptomycin has done well in spite of very small dosage. She is at a sanatorium in Switzerland. Her sinus has healed seven months after laparotomy with appendicectomy.

From all these cases the conclusion that can be drawn is that there is, as yet, no fixed rule for treatment of tuberculous tubes.

Rest, good food and heliotherapy all play their part. Though radical surgery is said to be of great value it may equally well be that surgery leads to a breakdown of protective barriers limiting the spread of the disease, to sinus formation and even to fæcal fistula. The attitude of the fœtus, suggesting intra-uterine death before it actually occurred, is of interest.

Had the correct diagnosis been made earlier, laparotomy before term might have resulted in a living fœtus. The high incidence of congenital abnormality in fœtuses resulting from ectopic pregnancy, noted by Von Winckel, necessitates the use of radiography to exclude this possibility, before laparotomy is carried out.

In abdominal pregnancy, which is indistinguishable from intraligamentary pregnancy before laparotomy, De Lee (1943) recommends laparotomy six weeks after term, as separation of placental adhesions to bowel may result in severe hæmorrhage in cases dealt with prior to fœtal death. However, the modern practice of leaving the placenta in situ when it is adherent to viscera has improved the results of the early operation.

Uterine Rupture.—Ian Donald, M.B.

A case of uterine rupture following a previous classical Cæsarean section is not in itself remarkable but this case presented certain rather interesting features; first the rupture occurred at the end of the very last pain with which the head was born and this in the second place produced an unusual and confusing third stage, as might be expected, and thirdly a manual removal of the placenta was unwittingly carried out without the large rent in the uterus being discovered.

The patient is a healthy woman of 38 who, three years previously, at the age of 35 had a classical Cæsarean section for a breech with extended legs, her somewhat elderly primiparity being an additional indication. It is known for a fact that the uterus was sutured with interrupted catgut.

In this pregnancy the vertex presented and as there was no disproportion it was decided to allow her to proceed to natural delivery. This she achieved in 25 hours

The girl who had streptomycin has done well in spite of very small dosage. She is at a sanatorium in Switzerland. Her sinus has healed seven months after laparotomy with appendicectomy.

From all these cases the conclusion that can be drawn is that there is, as yet, no fixed rule for treatment of tuberculous tubes.

Rest, good food and heliotherapy all play their part. Though radical surgery is said to be of great value it may equally well be that surgery leads to a breakdown of protective barriers limiting the spread of the disease, to sinus formation and even to fæcal fistula. It does appear that X-ray therapy has a definite place in the condition. How the treatment works may possibly be something like this:

Small doses of X-rays traumatize tissues and destroy the most sensitive cells which are the lymphocytes. There is a general reaction to remove the destroyed cells and a very low-grade aseptic inflammation is set up which helps to overcome the tuberculous infection which previously had not been adequately combated.

I should like to thank Mr. Rivett and Mr. Winterton who operated on several of these cases and who have so kindly allowed me to use their material and also Professor Windeyer and Dr. Japha who have helped in the compilation of this paper.

Full-term Intraligamentary Pregnancy.—I. T. FRASER, F.R.C.S.Ed.

Mrs. McD., aged 26, para 0. One previous miscarriage in 1943. Admitted to University College Hospital, 3.5.46.

Last menstrual period 10.8.45. Commencing one week later, the patient had slight vaginal bleeding, and shortly afterwards experienced pain in the right lower abdomen. At 11 weeks' gestation, two pieces of "membrane" were passed, and thereafter there was a brownish vaginal discharge.

At 13 weeks' gestation the patient was admitted to Watford Peace Memorial Hospital under the care of Professor F. J. Browne. Xenopus test was positive, and she was discharged four weeks later, pregnancy continuing. At 22 weeks' gestation, the fundus was at the level of the umbilicus, but no movements had been felt. Xenopus test was now negative. At 30 weeks' gestation, fœtal heart was not heard, and X-ray examination at Watford showed the fœtus to be lying obliquely in an attitude of extreme flexion. It was thought to be dead. Some brownish discharge continued to leak vaginally. The patient was admitted to University College Hospital at 38 weeks' gestation as a case of missed abortion.

Examination showed the fundus to be 2 in. above the umbilicus. The head was felt to the left side of the fundus but was not ballotable. Fœtal heart was unexpectedly heard, rate being 120. Vaginal examination revealed fœtal limbs, felt very easily in posterior fornix.

X-ray examination showed an oblique lie of the fœtus, with such flexion of the spine that the radiologist was convinced that the fœtus was dead.

The fœtal heart continued to be satisfactorily heard, and there was a slight watery discharge *per vaginam*. A tentative attempt at version without anæsthesia was unsuccessful.

Patient experienced slight lower abdominal pains on 21.5.46, the expected date of delivery. Next day the fœtal heart had ceased. During the course of the next few weeks, two medical inductions were given without success. Further X-ray at 44 weeks' gestation showed marked collapse of the fœtal skull.

Abdominal pregnancy was considered to be a possible diagnosis. The patient was examined under anæsthesia on 2.7.46, at 46 weeks' gestation, fœtal limbs being felt with great ease in the posterior fornix. The fundus uteri could not be distinguished separately from the main swelling. A dilator passed into the uterus for 5 in., further passage not being attempted.

DISCUSSION: MODERN METHODS IN THE CONTROL OF AIRBORNE INFECTIONS [*Abridged*]

Dr. R. Cruickshank: Airborne infection may be defined as infection by inhalation and includes many of the specific fevers besides respiratory infections proper. The present incidence of airborne infection is high. Although the *mortality* due to measles and whooping-cough has fallen steadily during the last fifty years their *prevalence* is probably as great as it was a century ago. It is likely also that there has been no diminution in the incidence of the less well-defined "acute respiratory diseases" such as colds, febrile catarrh and influenza and their secondary complications. In America members of widely different social and geographical groups have been found to have on an average three colds a year. In Great Britain several investigations have shown that 40 to 50% of the time lost from work or school is due to acute respiratory infections including influenza (Smith, 1934, two communities in Glasgow; Report, 1938, children in boarding schools; Report, 1946*a*, adults in wartime). These infections are therefore a source of great economic loss.

Community foci from which respiratory diseases may be introduced into the family are the school; the day nursery (Report, 1946*b*); the train, tube or bus; the office or factory; and the cinema or other place of entertainment. The risk of infection in such places can be estimated by bacteriological sampling of the air using *Strep. viridans* as an index of pollution (Buchbinder *et al.*, 1938). The detection of tracer substances volatilized in the air (Lidwell and Lovelock, 1946) allows frequent measurements of ventilation rates. There is need for correlation of these methods with careful sickness records among workers in a factory or large institution.

The relative importance of droplets, dust and droplet nuclei in the spread of infection is best assessed by eliminating one variable and noting the effect on the cross-infection rate. Spread by direct droplets is contact rather than airborne infection. It is perhaps not very important in streptococcal infections because throat carriers of hæmolytic streptococci do not expel many organisms when they cough or talk (Hare and Mackenzie, 1946). However, the classical experiments of Dr. Alison Glover on the control of epidemic cerebrospinal fever showed the value of reducing the risk of droplet spread by increasing the space between adjacent beds. Similar measures reduced by 50% the epidemic incidence of acute respiratory disease in new recruits in the American Army (Commission on Acute Respiratory Disease, 1946*a*).

Infected dust was shown to be important when the incidence of streptococcal cross-infection rate. Spread by direct droplets is contact rather than airborne dust control developed in England by van den Ende and his colleagues. Nasal carriers of hæmolytic streptococci appear to be the most important contributors to infection of the environment (Hamburger *et al.*, 1945, 1946). On the other hand dust-control measures did not prevent the epidemic spread of acute respiratory disease among troops in training (Commission on Acute Respiratory Diseases, 20 minutes of which only 1 hour 20 minutes were spent in an easy second stage. The very last pain was a strong one which both crowned and delivered the head in one, the shoulders and body being then extracted. The child, which was stillborn, weighed 7 lb.

Within two minutes the patient became profoundly shocked although no blood appeared at the vulva. The pulse disappeared at the wrist and the blood-pressure sank to 60/?.

Her condition was far too critical to do anything more than institute resuscitative measures. She was accordingly given oxygen, morphia and heat and the foot of the bed was raised and transfusion first with plasma and then with whole blood was commenced at maximum delivery rate both into the arm and leg.

From the time of the onset of the shock the abdomen was acutely tender and the fundus could not be felt and at no time was there any external bleeding and moreover the whole surface of the abdomen was resonant on percussion. Acute inversion seemed therefore the most likely diagnosis.

After two hours her condition had rallied sufficiently to warrant internal examination, the systolic blood-pressure being now just over 100. Accordingly an anæsthetic was administered.

On introducing the hand into the vagina a most peculiar elliptical slit was felt in the region of the cervix through which the hand could not be passed until a capsule of amyl nitrite had been broken under the anæsthetic mask. Following this the hand was able to follow the cord into the uterus where the placenta was found completely unseparated. It was of the battledore variety and was removed completely. A certain amount of bleeding accompanied this manœuvre but the uterus was rubbed up until a good contraction was secured and maintained with ergometrine and further bleeding *per vaginam* ceased.

The transfusion was continued and one and a half hours after the removal of the placenta she had had in all 2 pints of plasma and 4 pints of blood; she looked less pale, her pulse was 100 and her blood-pressure 115/75 but on examining her the fundus could not be felt and yet there was no sign of any bleeding *per vaginam*. Moreover, for a woman who had just received so much blood her condition was not good. Some fullness was noticed in the flanks and she complained of pain across both shoulders, especially the right. On percussion there was unmistakable dullness in the flanks. The abdomen felt doughy but the physical signs had been obscured by the administration of morphia.

A diagnosis of ruptured uterus was made with hæmoperitoneum, and laparotomy was forthwith undertaken. The peritoneal cavity was found indeed to contain a very large quantity of blood and the uterus was found to have ruptured throughout the entire length of the previous Cæsarean section scar.

Subtotal hysterectomy was rapidly carried out and the patient made an uninterrupted recovery. Total transfusion amounted to 8½ pints.

The section shows chorionic villi in relation with the ruptured scar, with large areas of fibrous tissue much of which is very degenerate.

I would like to thank Dr. Wrigley for permission to describe this case and also for the help and moral support which he gave at the time.

The section shows chorionic villi in relation with the ruptured scar, with large areas of fibrous tissue much of which is very degenerate.

I would like to thank Dr. Wrigley for permission to describe this case and also for the help and moral support which he gave at the time.

little killing at low concentrations, then a rapid increase and finally a relatively constant maximum. (2) Relative humidity exerts a dominant effect giving maximum killing between 60% and 80%. A rapid fall in killing rate below 50% relative humidity considerably reduces the effectiveness under many working conditions. (3) Increase in particle size diminishes the killing rate. (4) The nature of the particles also affects the rate, which is low with dry dust particles, intermediate with natural sprayed salivary flora, and very high with sprayed cultures. Different species of organisms vary in sensitivity. In field trials most airborne organisms are dry, dust-borne and resistant.

Dr. M. Mitman had found that a germicidal mist of resorcinol generated in a cubicle by a simple apparatus, the aerovap, failed to give significant reduction in the numbers of organisms and hæmolytic streptococci falling on exposed plates. Nevertheless, he felt that intermittent aerial disinfection at the times of activities known to cause peak infection would be a valuable method of preventing spread of infection from cubicle to corridor.

Major A. C. Cunliffe described an experiment which was made during an outbreak of infection with *Strep. pyogenes*, types 4 and 12, in a ward of children undergoing plastic operations of the palate, in which oil-treatment of the bed-clothes was associated with a marked reduction in the numbers of airborne streptococci and a significant decrease in the cross-infection rate. In the six weeks before the application of oiled bed-clothes the average number of *Strep. pyogenes* isolated by a slit sampler during bed-making was 22·6 ± 8·1 per cu. ft. of air, while all 16 post-operative patients were found at routine swabbings to have acquired *Strep. pyogenes* (a cross-infection rate of 100%). In the following nineteen days when all bed-clothes were oil-treated, the average number of streptococci was 0·7 ± 0·24; 5 (41·7%) of 12 patients were cross-infected. In the next three weeks when unoiled bed-clothes were used the average number of streptococci rose to 2·7 ± 0·8 and 70·6% of 17 patients were cross-infected.

Dr. J. L. Burn showed photographs illustrating some points in the prevention of airborne infection in schools and day nurseries.

Dr. J. M. Alston did not agree that acute respiratory disease could be attributed entirely to airborne infection. Endogenous infection and contact spread were important, and contaminated hands and handkerchiefs probably played a large part. Impregnation of handkerchiefs with penicillin or other antibacterial substance seemed worth experiment.

Dr. William Gunn commented on Dr. Wright's results and conclusions stressing that significant differences between test and control groups could be expected only when atmospheric contamination was high. Under present conditions a certain amount of infection was to be expected especially in highly susceptible children. Oiling of floors and fabrics was the only practicable method available for suppressing dust.

Professor Ronald Hare said that in United States Army and Navy barracks ultraviolet light and triethylene glycol aerosols had failed to produce any dramatic reduction in upper respiratory tract infections. Prevention of a very infectious virus disease such as influenza might be much more difficult than prevention of a microbic infection such as scarlet fever. Wide variations of attack rates occurred in comparable groups of persons without control measures, and therefore prolonged investigations would be necessary before any particular prophylactic could be said to have achieved its object.

1946*b*). Therefore spread by dust may be more important in bacterial than in virus infections.

Droplet nuclei are probably the usual mode of spread of virus infections where the infecting dose is small. Control of droplet nuclei by ultraviolet light has been achieved in America in the case of measles in school classrooms (Wells, Wells and Wilder, 1942) and of respiratory infections in infants at the Cradle Hospital.

The application of new methods of attack on the channels of airborne infection is enlightening the darkness that envelops this complex problem and we may take pride in the knowledge that many of the advances have originated from work done in this country.

Dr. Joyce Wright discussed two trials of dust-control measures in measles wards. In the first trial (Wright *et al.*, 1944) oiling of blankets, bed linen, garments and floors in one ward reduced the bacterial and hæmolytic streptococcal counts of the air during bed-making to 91% and 98% respectively below those in a control ward. The streptococcal cross-infection rate was lower in the oiled ward than in the control (18·6 *versus* 73·3%) as was the rate of otorrhœa due to streptococcal cross-infection (2·8 *v.* 14·3%). Most cross-infections were due to type 6 streptococci. In the second trial (Begg *et al.*, 1947) bacterial counts in the control ward were low and there was less difference between them and counts in the oiled ward. The streptococcal cross-infection rate was higher in the oiled ward than in the control ward (20·5 *v.* 12·4%). The cross-infections were due to different types of streptococci and probably to contact spread. More cases with skin sepsis and streptococcal otorrhœa were admitted to the oiled than to the control ward despite alternate allocation of new patients. Dust-suppressive measures may be useful in measles wards if there is a high incidence of streptococcal infection.

Mr. F. Courtney Harwood emphasized that good laundering methods are essential if oiling of fabrics is to be satisfactory. Oiling is a simple process if goods are washed and rinsed and softened water is used. Blankets can be steam sterilized without loss of oil. He said that research into laundering methods was continuing.

Dr. O. M. Lidwell discussed the results of laboratory tests of α-hydroxy-carboxylic acids as aerial disinfectants. Details will be published elsewhere. The bactericidal effect can be represented by a logarithmic killing curve and calculated as "equivalent air changes per hour." The resultant reduction of the contamination of air in a room depends on the pre-existing rate of removal of bacteria-carrying particles by ventilation and sedimentation. In order to halve the mean concentration of bacteria-carrying particles, it is necessary to double the overall rate of removal.

Four important factors affect the killing rate of α-hydroxy-carboxylic acids. (1) Increase in concentration of the bactericide usually gives an S-shaped curve with little killing at low concentrations, then a rapid increase and finally a relatively constant maximum. (2) Relative humidity exerts a dominant effect giving maximum killing between 60% and 80%. A rapid fall in killing rate below 50% relative humidity considerably reduces the effectiveness under many working conditions. (3) Increase in particle size diminishes the killing rate. (4) The nature of the particles also affects the rate, which is low with dry dust particles, intermediate with natural sprayed salivary flora, and very high with sprayed cultures. Different species of organisms vary in sensitivity. In field trials most airborne organisms are dry, dust-borne and resistant.

Dr. M. Whooping Cough and Measles

An Epidemiological Concurrence and Contrast

By WILLIAM BUTLER, M.B.
(*Brevet Lieut.-Colonel, Retd.*)

THERE is an intimate association of whooping cough and measles. They are coupled in the popular mind as affections of childhood, normally to be expected almost as inevitably as those of teething. Familiarity had bred a contempt which their comparatively low case fatality appeared to condone and yet at the time when this contempt most prevailed their respective contributions to child mortality were each of them higher than those of any other infectious disease. One hundred years ago, whooping cough exacted on an average each year in round figures 500 deaths per million population and measles over 400, to-day their mortality has fallen respectively to about 30 per million. The decline in mortality set in earlier in the case of whooping cough and its quinquennial rates have been uninterrupted in their progressive fall during a period of over 60 years. Measles, which lagged in its decline until the beginning of the present century and at the beginning was less steady in its fall, has nevertheless during the last quarter of a century sustainedly reduced the lead until now the respective annual mortality contributions are about equal. It has long been noted that the mortality among females was higher than that of males in whooping cough and lower in measles. The decline throughout a prolonged period in mortality for each sex in both diseases has maintained the respective sex ratios, though if the crude death-rates of each sex at all ages be taken, the positions with regard both to measles and whooping cough are reversed in the years of the first Great War.

Batch fatality rates.—It is an obvious advantage to have recorded the case fatalities from current diseases continuously throughout the period of their occurrence. A rate relating deaths to the actual cases from which they derive, where that is possible, is the most reliable statement of case fatality.

The batch fatality rate computed by the method described in a paper on "The Fatality Rate of Measles" (*J. R. statist. Soc.*, 1945, **108**, Pts. 3 and 4) gives, I believe, a very close approximation to this result. It is true of the batch fatality rates advancing *seriatim* week by week with the returns that they assume the character of a moving average picking up belated deaths and dropping others which later are ascribed as fatalities of subsequent batches. This has the effect of slightly flattening the curves described by the varying rates but, if the pre-fatal interval obtains in anything like the proportions I have assumed on the bases of the somewhat limited analysis which has been available, the instances which do not strictly belong to the batch period must be very few in number. In any case, the rates do exhibit, very closely to what is actually occurring, fluctuations which with the same approximate accuracy are shown by no other method with which I am acquainted.

In an analysis made between thirty and forty years ago of 196 deaths from measles and of 187 deaths from whooping cough I found that while in measles 93% of the deaths had occurred by the end of four weeks from onset, only 75% of the deaths from whooping cough had occurred within that period. For this and for other reasons I considered that in the case of measles it was sufficiently near the facts to assume that if a fatal termination were to occur it would do so within five weeks of onset, which gave a batch period of nine weeks and a fatality term of five weeks and on this assumption the formula for calculating the batch fatality rate was constructed (*J. R. statist. Soc.*, 1945, **108**, Pts. 3 and 4). The error in the case of measles was negligible so far as the few cases dying outside these limits was concerned. In the case of whooping cough the difficulty of determining a period within which all fatalities would occur was greater. 25% of the fatalities occurred beyond the fourth week of onset of the disease and it is practically certain that not all—if even the greater part—of the remaining fatal cases would die within another week as might be practically assumed of the smaller residue in the case of measles. On the other hand the further the batch period was extended beyond that within which the bulk of the remaining fatalities actually occurred, the less definite was the relationship of the batch to the deaths to which it was presumed they were specifically related. Moreover, the deaths ascribed to whooping cough are more inclusive of all fatalities from this disease than are the returns of measles of the actual cases of death from morbilli, and for this reason: the chief causes of death from either of these affections are pulmonary complications. The diagnostic evidences of measles disappear with the eruption but those of whooping cough obtrude themselves for weeks after the onset of the disease. As a result pulmonary affections are recognized as secondary in higher proportion in the case of whooping cough: in measles the primary affection may never have been recognized, its diagnostic evidences having disappeared before medical aid was sought. It follows that the number of cases of whooping cough dying at the more remote periods from onset are recognized as such in greater proportion than in the case of measles. In assuming that whooping cough has a six weeks' fatality term, necessary for practical purposes, it has to be recognized that a higher, though relatively a small, proportion of the deaths which should be totalled in the six weeks' fatality term from cases occurring during the batch period of eleven weeks are carried over and included in succeeding fatality terms. This has the effect greater than in the case of measles of slightly flattening the curve of case fatality rates. Nevertheless it remains approximately correct and is a useful, though not an exact, figure. The batch fatality rates of measles and of whooping cough have been calculated for each week over the six complete years, 1940-45, during which these diseases have been notifiable (Table I). They are based on the Registrar-General's returns for London and the Great Towns and the respective formulæ used were:—

FORMULA FOR CALCULATING BATCH FATALITY RATES

Where serial cases and deaths are recorded week by week as in the Registrar-General's weekly returns of notifications, the batch fatality rate at the terminal week of each successive—Measles: 9-weekly, whooping cough: 11-weekly—period is:—

MEASLES

$$\frac{\text{The sum of the deaths during last five weeks} \times 1{,}000}{\text{(Half the sum of the cases of the first four weeks + all the cases of the middle week + half the sum of the cases of the last four weeks)}}$$

WHOOPING COUGH

$$\frac{\text{The sum of the deaths during last six weeks} \times 1{,}000}{\text{(Half the sum of the cases of the first five weeks + all the cases of the middle week + half the sum of the cases of the last five weeks)}}$$

Seasonal variations in fatality.—Perhaps the most outstanding feature of the batch fatality rates as well of measles as of whooping cough is the regular, and in the uniformity of behaviour, definitely characteristic variations with season.

As will be seen from Table I and fig. 1 there is a close correspondence in the seasonal variations of fatality in the two diseases. In both, fatality is lowest in the warmer months of the year. Measles falls below the mean earlier (May) than whooping cough (June) and the case fatality of whooping cough appears to be less adversely affected by late autumn than that of measles.

EXPLANATION OF GRAPHS

The graphs are of the differences, expressed as a percentage above or below the six-yearly mean, between the weekly numbers of cases averaged for each month and the weekly numbers of cases averaged for six years. The course of incidence, just as if of the actual monthly mean of weekly numbers, is shown in three successive biennial periods, either singly for each biennial span or by superimposition of three successive biennial graphs. The composite graphs are of the means of the cases so graphed and respectively comprised in the three successive biennial periods.

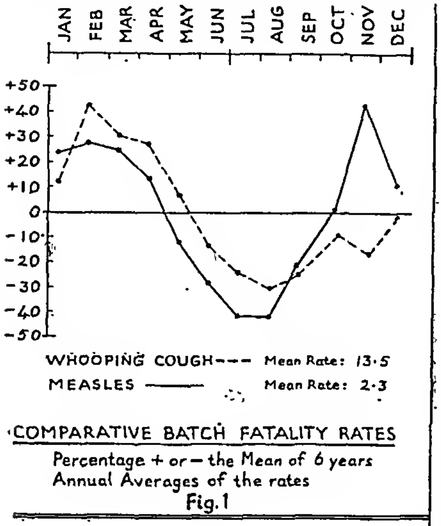

FIG. 1.

MEASLES

Fig. 5. Superimposed biennial distribution — 6 years →

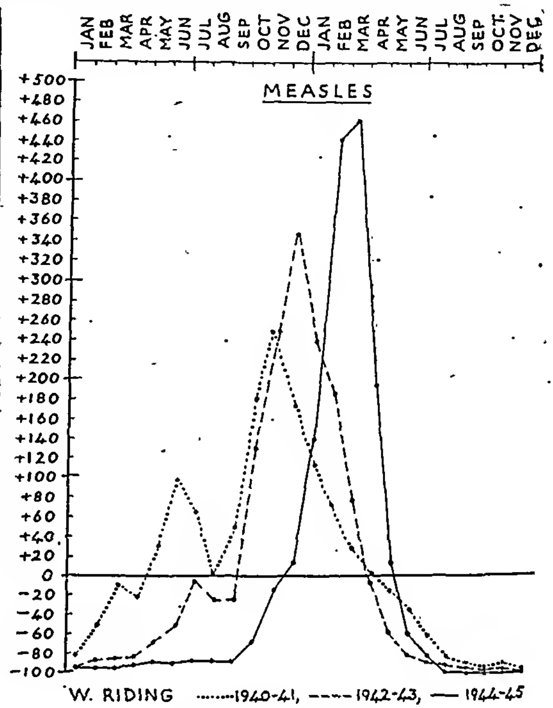

FIG. 5 (*see also* fig. 4).

Taking consecutive months in each third of the year, the four months, May to August, are more favourable to measles than to whooping cough which, in its batch fatality rates averaged for the period, has a multiple 7·2 times the batch fatality rates similarly averaged for measles. The first four months of the year are next more favourable to measles with a whooping cough ratio 6·0 times the average batch fatality rates of measles, while in the last four months, measles is relatively much more adversely affected, the multiple of whooping cough to measles average batch fatality rates falling to 4·8 times.

In Table II are set out the maximal and minimal rates among the serial batches of each year and the months in which they occurred:

TABLE II.—WHOOPING COUGH AND MEASLES MAXIMUM AND MINIMUM BATCH FATALITY RATES PER 1,000.

		Maximum during year	Month of occurrence	Minimum during year	Month of occurrence	The averaged mean of monthly B.F.R.s each year

Yearly decline in case fatality.—Throughout the six years, the batch fatality rates both of measles and of whooping cough are unexpectedly low. The continuing decline from previously accepted rates to the low figures of the notification years is still to be observed as a process common to both diseases. During the notification period the measles batch fatality rate has declined by about one-third, that of whooping cough by about one-fourth.

If we turn from batch fatality rates to case fatality calculated on the annual totals of cases and deaths from either disease during each successive year, confirmation of this trend is disclosed and the behaviour of the rates not only of London and the Great Towns but of England and Wales also can be observed (Table III). Although case fatality rates calculated on these data, comparable over so prolonged a period, differ slightly from the batch fatality rates averaged for similar periods (Table I), they both'tell the same tale.

TABLE III.—RATIO OF ANNUAL TOTALS OF DEATHS TO CASES FOR ENGLAND AND WALES AND LONDON AND GREAT TOWNS, MEAN ANNUAL BATCH FATALITY RATES, LONDON AND GREAT TOWNS AND WHOOPING COUGH MULTIPLES OF CORRESPONDING MEASLES RATES.

1945	,,	11·5	6·4		11·1	5·9		11·0	6·9	
	,,	1·8			1·9			1·6		

It is to be noted, however, that the high batch fatality rates of whooping cough in the early months of 1940, never afterwards approached, are, relatively to subsequent rates, probably exaggerated. Statutory notification of whooping cough and measles, recently imposed, was almost certainly less complete in the earlier months of its operation than later. There is, in the case of whooping cough, an additional lag due to the fact that notification is usually delayed until late when the whoop has developed. The diminution due to this delay is, when notification has got into its stride, in some measure, compensated by the legacy of preceding similarly-acting deferment. It is probably for this reason also that the annual averages of the monthly batch fatality rates give for the year 1940 a rate very considerably in excess of the case fatality calculated from the smoothing annual totals of cases and deaths. The year 1940 is the only one in the six years' series, in which there is a difference in the annual rates calculated by these respective methods, so great that it would show to the first place of decimals in rate, as commonly expressed, of deaths per 100 cases.

Measles fatality, it will be seen from the tables, is falling more rapidly than the case fatality of whooping cough both in the Great Towns, and in England and Wales. This retardation, relative to that of measles in the decline of whooping cough fatality, is the more clearly seen if, in the successive two-yearly periods in which the measles epidemics respectively run their course, the ratio of the fatality rates of the two diseases in the relative years is compared.

Case fatality in hospitals—M.A.B. and L.C.C.—The most reliable figures of case fatality in the pre-notification period come from hospitals where the numbers of cases and deaths are known precisely (Table IV). Unfortunately, however, owing to the selective character of the cases, these, in many respects, are not comparable with figures which would have been yielded by corresponding cases and deaths among the general population.

TABLE IV.—CASE FATALITY IN M.A.B. AND L.C.C. HOSPITALS.

Figures by courtesy of Sir Allen Daley.

Measles fatality has declined in hospital more rapidly than whooping cough though both continue to fall; and right up to the present time, as shown also by batch fatality rates, the reduction in case fatality is for both a striking and even an astonishing feature.

Persistent as for many years, within the limited field of observation possible, has been the decline in case fatality, notification revealed, at least in the case of measles, a fall which must be regarded as abrupt. This I have already discussed (*J. R. statist. Soc.*, 1945, **108**, Pts. 3 and 4). With regard to whooping cough, in a personal communication from Sir Allen Daley he says “that the sharp fall in case fatality in 1939 was shared by the whole community” and in support of this says, “Some comparison of the incidence of whooping cough in 1938 and 1939 can be made from the reports of cases noted by head teachers at schools, though these reports ceased to be complete after the middle of 1939, owing to the dispersal of school children. For the first six months of each year the figures are 2,025 in 1938 and 7,125 in 1939. Thus in the first half of 1939 the incidence was three times as heavy as in the same period of 1938. Deaths in the first half of 1939 were 91 compared with 72 in the first half of 1938, whereas the expected figure on 1938 case mortality would be in the region of 250”. Case fatality on the above figures shows a fall of from 35 to 13 per 1,000 and is thus quite as striking in whooping cough as in measles.

In measles there seems good reason to believe that the decline in case fatality is in considerable measure due to changes in age-incidence, and it is possible that whooping cough fatality, which has behaved in like manner may be similarly accounted for. Dispersal of children which was so marked a feature of 1939, diffusing infection of measles, of whooping cough and other diseases among persons normally less in contact with infection and of higher age-periods than school children, hitherto the most intensively exposed, may well account for the abrupt fall in case mortality in both diseases. Stocks has shown that the dispersal of children had the effect in certain regions of keeping down the whooping cough rate in the evacuation towns, but in the reception areas evacuees with a higher incidence were mingling with an adult population less protected than that from which the children had been evacuated. It is not the whole story. There are other factors persistently modifying the course and character of these familiar epidemic diseases, but the dispersal of juveniles both in the evacuation and in the reception areas at the outbreak of war was calculated to produce just such striking results as we have observed.

Age distribution of cases.—So far we have considered the behaviour of case fatality at all ages. It has for long been established that both diseases are much more fatal in early than in later life and the case distribution according to age becomes important on this account, since case fatality will be higher the greater the proportion attacked at the more vital age-periods. I have been able to cull a random sample of some 15,000 cases of whooping cough and 33,000 cases of measles from recent annual reports of those relatively few Medical Officers of Health who have set out their analyses.

TABLE V.—AGE DISTRIBUTION OF APPROXIMATELY 15,000 CASES OF WHOOPING COUGH AND 33,000 CASES OF MEASLES.

†Figures in Registrar-General's Quarterly Returns.

The figures relate to cases of whooping cough and measles taken at random throughout England and Wales. In place and period their respective occurrence was identical. Those relating to Rural Districts are small but sufficient, I think, to reflect with approximate truth the differences between urban and rural incidence of these diseases. I have added to the table the figures of another and quite different random sample I had previously recorded (*J. R. statist. Soc.*, 1945, **108**, Pts. 3 and 4) of measles notifications similarly distributed. The almost identical proportions of distribution in these different samples is presumptive that they are characteristic. I think the figures demonstrate some important features in the recent behaviour of the two diseases.

(*a*) Whooping cough attacks infants in much higher proportion than does measles and both have higher incidence upon urban than upon rural infants.

(*b*) The proportion of persons attacked over 5 years of age is considerably higher in measles than in whooping cough and is much higher in the former than, before notification came into operation, one would have expected. Again the proportion is higher in rural districts than among urban populations.

During the first 6 months of life infants are little susceptible to measles but no such protection is afforded against whooping cough, in fact susceptibility to this disease in early childhood appears to be exceptionally emphasized. In the 0 to 5 age-group children are attacked in very much greater proportion in towns than in rural districts, as might be expected. Since liability to attack when exposure occurs must, in children not already protected by previous attack, be pretty much the same in both diseases and since opportunity of exposure must, in the more prevalent measles, be greater, it is difficult to understand why early childhood should be selected to bear the brunt of whooping cough and even though no congenital immunity in the early months of infancy safeguards the baby from this disease its native seclusion should afford sufficient protection save when other members of the family become affected. I have also included in the table the ratios of age-incidence of measles and whooping cough for England and Wales. It will be seen that the proportions to those at all ages, at the respective age-periods given in the random sample, are in agreement with those shown by the much more comprehensive figures, which, in fact, give ratios intermediate between those of urban and rural districts, not distinguished in the figures for England and Wales.

Sex incidence.—The ratios of male to female cases in all age-groups in 1944–46 are distinctive for the two diseases, and show very little variation with age except in the over 15 age-group in which the numbers of cases are small.

Unfortunately corresponding distribution of deaths is insufficiently available to enable case fatality at age-periods to be calculated on a scale that is adequate. London hospital figures (M.A.B. and later L.C.C.) show how at each age-period case fatality has been declining during the last thirty years.

TABLE VI.

Measles fatality has declined in hospital more rapidly than whooping cough though both continue to fall; and right up to the present time, as shown also by batch fatality rates, the reduction in case fatality is for both a striking and even an astonishing feature.

Persistent as for many years, within the limited field of observation possible, has been the decline in case fatality, notification revealed, at least in the case of measles, a fall which must be regarded as abrupt. This I have already discussed (*J. R. statist. Soc.*, 1945, 108, Pts. 3 and 4). With regard to whooping cough, in a personal communication from Sir Allen Daley he says "that the sharp fall in case fatality in 1939 was shared by the whole community" and in support of this says, "Some comparison of the incidence of whooping cough in 1938 and 1939 can be made from the reports of cases noted by head teachers at schools, though these reports ceased to be complete after the middle of 1939, owing to the dispersal of school children. For the first six months of each year the figures are 2,025 in 1938 and 7,125 in 1939. Thus in the first half of 1939 the incidence was three times as heavy as in the same period of 1938. Deaths in the first half of 1939 were 91 compared with 72 in the first half of 1938, whereas the expected figure on 1938 case mortality would be in the region of 250". Case fatality on the above figures shows a fall of from 35 to 13 per 1,000 and is thus quite as striking in whooping cough as in measles.

In measles there seems good reason to believe that the decline in case fatality is in considerable measure due to changes in age-incidence, and it is possible that whooping cough fatality, which has behaved in like manner may be similarly accounted for. Dispersal of children which was so marked a feature of 1939, diffusing infection of measles, of whooping cough and other diseases among persons normally less in contact with infection and of higher age-periods than school children, hitherto the most intensively exposed, may well account for the abrupt fall in case mortality in both diseases. Stocks has shown that the dispersal of children had the effect in certain regions of keeping down the whooping cough rate in the evacuation towns, but in the reception areas evacuees with a higher incidence were mingling with an adult population less protected than that from which the children had been evacuated. It is not the whole story. There are other factors persistently modifying the course and character of these familiar epidemic diseases, but the dispersal of juveniles both in the evacuation and in the reception areas at the outbreak of war was calculated to produce just such striking results as we have observed.

Age distribution of cases.—So far we have considered the behaviour of case fatality at all ages. It has for long been established that both diseases are much more fatal in early than in later life and the case distribution according to age becomes important on this account, since case fatality will be higher the greater the proportion attacked at the more vital age-periods. I have been able to cull a random sample of some 15,000 cases of whooping cough and 33,000 cases of measles from recent annual reports of those relatively few Medical Officers of Health who have set out their analyses.

activity maintaining at lower levels an endemic continuum. To this latter type both whooping cough and measles belong and in this respect differ from intermittent invaders such as, in Europe, are cholera, plague, smallpox and other occasional visitors. A succession of Registrar-Generals, and their medical advisers, have given voluminous, invaluable records, mostly in terms of deaths, of the courses and other epidemic features of measles and whooping cough in England and Wales. Six years of statutory notification of measles and whooping cough on an inclusive basis throughout England and Wales have placed for the first time at the disposal of investigators a store of facts which enables case distribution to be shown on a scale not only not hitherto available but on one sufficiently comprehensive to give a presumption of the distribution being characteristic. The six years' notification records relate to a period—war and post-war years—in which conditions affecting prevalence have been far from normal. It is possible, therefore, that we are dealing with somewhat atypical epidemic occurrences and so it would be wrong to assert of observed fact anything but its current truth. Nevertheless the broad features at least of measles epidemics appear not to have altered. I have made (*see Monthly Bull. Min. Hlth.*, April 1946) a comparison of graphs showing the composite weekly means of notified cases of the three epidemics of measles, London and the Great Towns 1940–1945, and the composite weekly means constructed from deaths and school-notified cases of three epidemics, London 1908–1913. As may be seen by reference to the graphs (reproduced with the article) the respective epidemics follow a common course in which resemblance in all outstanding features is very striking. Measles more than whooping cough exhibits repetitive epidemic features, though it is possible that in the case of whooping cough the gamut of the notification period is insufficient for the development of periodicity analogues, if, in fact, they occur.

Differences in the epidemic course, shown respectively by deaths and cases.—Comparison of corresponding graphs of cases and of deaths similarly plotted bears out what would be expected from consideration of the differences in seasonal case fatality. Taking the extreme range in the case fatality exhibited, that between the end of August 1945 and the end of January 1946, the batch fatality rates were found to vary from 0·2 to 7·6 per thousand. "A given number of deaths would at the lower rate yield a total of cases 38 times the number calculated at the higher rate" (*Monthly Bull. Min. of Hlth.*, May 1946). With a mean number of weekly deaths of 15 the calculated number of cases per week would, with this range of case fatality, vary from 2,000 to 75,000 and this potentially wide range of error, where a flat rate of fatality had to be assumed, inevitably must greatly disturb seasonal distribution when deaths are translated into calculated cases. The monthly distribution respectively of cases and of deaths each as a proportion of their respective six years' means does not, however, as may be seen from the diagrams, so greatly vary the main epidemic features that they are not in each series clearly exhibited. Taken separately either for the two-yearly periods within which each of the three epidemics ran its course (fig. 2, *a*, *b*, and *c*) or, for the average figures (fig. 2, *d*), seen in the six-yearly composite graphs, these features, characteristic of measles, are easily perceptible whether the graphs be of deaths or of cases. Alike, in contemporary and in successive epidemics, the minor and the major phases, the summer maximum of the minor phase, the autumnal notch, the re-commencing ascent in September–October, the maximum peak of the second year and thereafter the rapid fall and maintenance for several months in late autumn and early winter of a low, practically uniform level of sub-epidemic or endemic prevalence are common to all graphs. Nevertheless, differences and distortions of proportionate prevalence are shown in the death graphs as compared with those of actual cases. In the winter months, except when anomalous low fatality occurs, the graphs of deaths are relatively much higher and in the months of low case fatality proportionately lower than the graphs of cases. This has the apparent effect in the deaths graphs of greatly reducing the volume of the minor phases which attain their maxima in the summer months of low fatality, when cases are represented by few deaths, and of lengthening the peaks of the major phases which coincide with months of high case fatality when a given number of cases are represented relatively by more deaths. This, of course, is what we should expect and without more than indicating the kind and magnitude of these differences we may pass to consideration more fully of the graphs in which they are displayed.

The graphs.—During the six completed years within which statutory notification has operated—1940–45—all the epidemics of measles have bestridden the calendar divisions between years in each of all three successive biennial periods. The complete course of an epidemic, therefore, could be exhibited only in a span which included parts at least of two successive years. It was found that the beginning of the first year of each such span coincided approximately with a commencing epidemic rise, immediately following a sub-epidemic level sustained during several preceding months. Commencing at the beginning of one year each epidemic attained maximum incidence in the next and, some months before the end of the year, subsided, to just such a level as that from which it sprang.

TABLE VII.—ENGLAND AND WALES.

Whooping Cough and Measles Notifications. Proportional Age and Sex Distribution on Totals of 1944, 1945 and Six Months of 1946

	All ages	0–1	1–3	3–5	5–10	10–15	15 and over
				Whooping Cough			
Sex ratios 100 F/M	112	101	108	112	112	120	331
Proportion all ages =	100	M 11·1 F. 10·1	28·3 27·5	27·5 27·6	30·1 30·8	2·4 2·6	0·8 2·3
				Measles			
Sex ratios 100 F/M	100	97	94	97	99	110	203
Proportion all ages =	100	M 4·3 F 3·9	22·6 21·2	26·1 25·2	40·5 40·2	5·0 5·5	2·8 4·2

As already pointed out hospital figures in many respects are not comparable with those relating to the general population. For well-known reasons they are higher, but there can be little doubt that they reflect at the times to which they relate, and in their respective age proportions, analogues in rates which differ from those of the general population principally in their order.

One fact of great interest remains unaffected by recent data. The established high fatality of both diseases in the first two years of life, greater in the case of whooping cough and especially in infants, is perhaps, from the point of view of preventive practice, the most significant feature in their behaviour. That whooping cough is more deadly even than measles in the first year of life is in part due to the fact that while most infants have a respite from measles during the first six months no such congenital immunity is extended to whooping cough. Approximately whooping cough has twice the opportunity in time to claim its fatalities in the first twelve months of childhood. There is for the young infant no compensatory protection from whooping cough which the sex of the mother predisposes her to contract and—whether on this account or not—in higher proportion than the male sex to die of the disease. Immunization of the mother by actual attack appears not to be as in measles congenitally transmissible even for a brief period. Moreover as Stocks has pointed out (*J. Hyg.*, 1932, 32) "the loss of acquired latent immunity is more rapid than in measles and little or none remains after a year". In measles apparently it lasts for two or three years. Not only the acquired latent variety but the active immunity conferred by attack appears subject to the same rule. I myself have been the victim of three attacks of whooping cough at intervals approximately of twenty-five and forty-five years respectively between the first and second and the second and third occurrences. This is doubtless very exceptional though I have known of a number of adults who have suffered attack notwithstanding that in childhood they had undergone a primary salting. In measles second attacks are rare; in whooping cough acquired immunity is permanent to a lesser degree than the high protection extended usually for life in the case of measles.

Immunities, congenital, latent or active following fully developed attack are co-determinants of epidemic developments and endings. With apparently universal susceptibility to whooping cough from birth, and to measles after six months of congenital protection, these diseases are the commonest and most widespread of the scourges of childhood. Deferred to the ages and seasons of low fatality, therapeutically cared for on a scale co-extensive with that of diffusion, there is, as a growing trend reflected in lower and declining fatality demonstrates, a prospect of protection to the community at a sacrifice which is but a fraction of that hitherto claimed. It is neither practicable nor desirable wholly to prevent diffusion throughout the community of ever-present infections to which all, until immunity has been acquired, are highly susceptible. It looks as though the time may not be distant when such immunity may be conferred by specifically directed measures. Till that is possible preventive efforts should consist, not in futile attempts by time-honoured but inappropriate means aimed at limiting immediate diffusion from cases, for this purpose belatedly coming to knowledge, but rather in noting the natural behaviour of these diseases by appropriate social and other administrative adjustments, so arranging that as far as possible the inevitable personal attack befalls when it is least dangerous to the patient.

EPIDEMIC BEHAVIOUR

The epidemiologist is concerned with the incidence of communicable diseases as seen affecting masses of the population. Their prevalence may be sporadic, epidemic, endemic or of a mixed description as when, between epidemic exacerbations there is a sub-epidemic

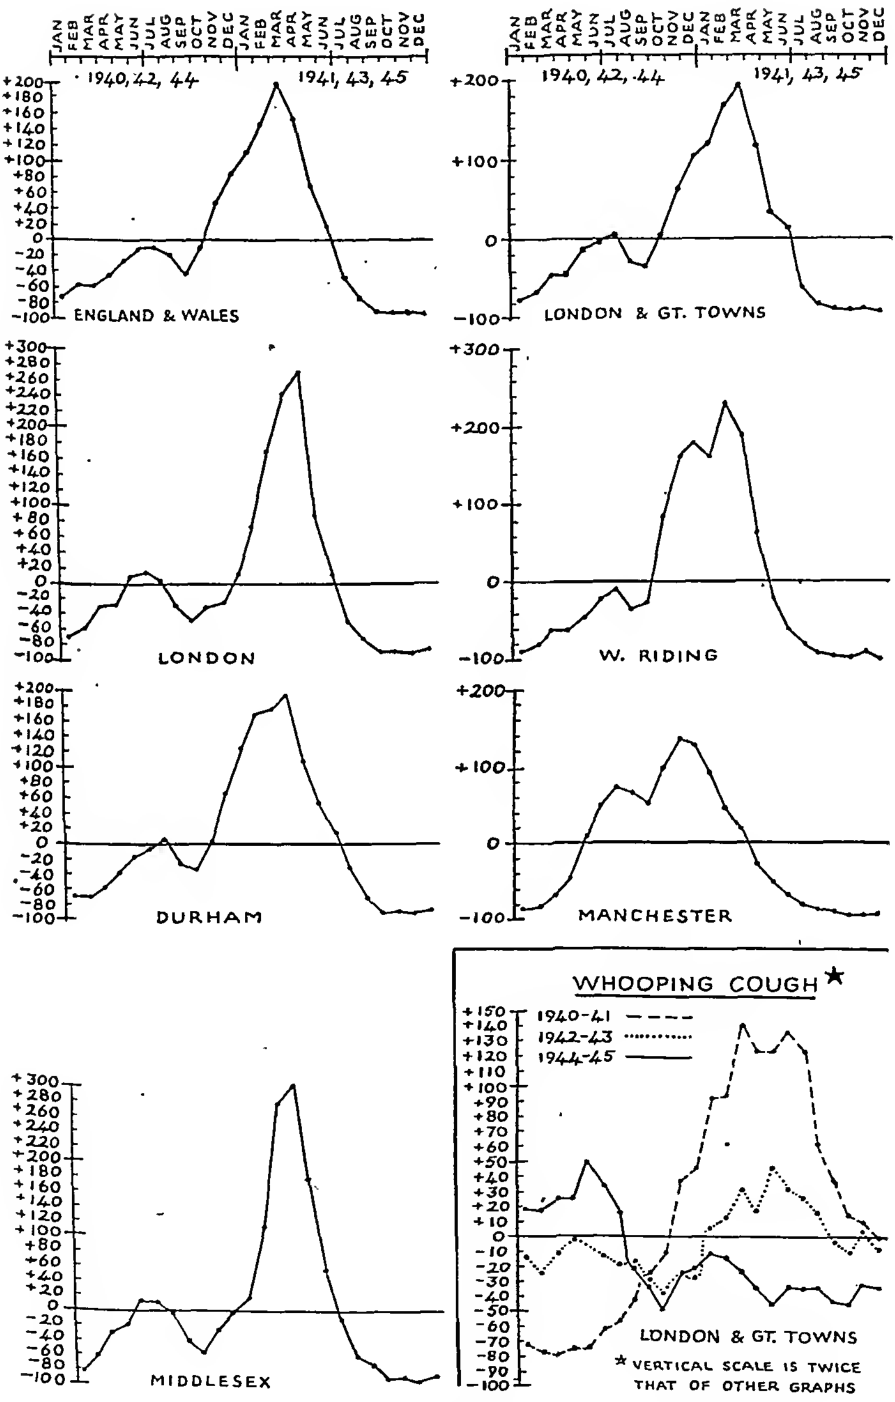

Fig. 3

MEASLES. Composite of Three Epidemics. Years 1940-1945.

(*b*) (*d*)

MEASLES. LONDON AND GREAT TOWNS. Respective graphs of cases and deaths.

that month was the break, not in the ascent but in its steepness previously uninterrupted from April to July. In the epidemic, 1942–43 (fig. 4*c*), again in Manchester, which acts to-day as England may to-morrow, the customary minor phase in May attained a maximum higher than that reached in the December of what usually is the major phase. That in London again the minor phase of the epidemic, 1940–41 (fig. 4*b*), was atypical, almost lacking in fact, was due no doubt as were other atypical developments of the epidemic to the very extensive evacuation of children which then characterized the metropolis.

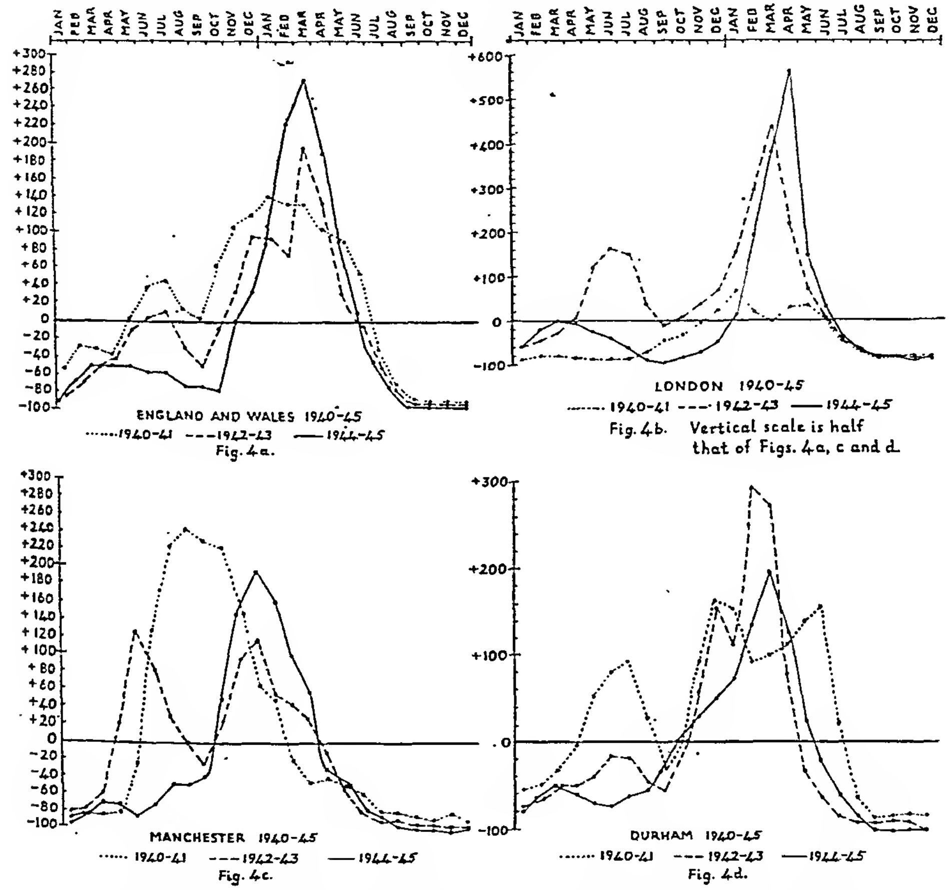

Fig. 4a. Fig. 4b. Fig. 4c. Fig. 4d.

FIG. 4 *a*, *b*, *c* and *d*.—MEASLES. Superimposed biennial distribution—6 years.

It is to be noted that in none of the instances, in which these aberrant forms were presented, did the composite graph of the other two of the three epidemics depart from the type to which the others in the six years' records of the prevalence conform. Further, the chronological order of development in the aberrant types may vary and in their maximal incidence revert exceptionally to a season noted in the past as common and yet in general feature resemble what is claimed as the unmistakable type of current measles. It is as though, if one may import an animism, that when conformity to type was thwarted, a corrective reaction marked subsequent activities.

The sub-epidemic phase.—There is one other feature of the graphs of measles to which attention should be directed, a negative one, but different from the others in that it does not vary and so is common to all the graphs. In the September of the second year of epidemicity, incidence has fallen rapidly as a rule, to a level from which on the scale on which the graphs are drawn there is scarcely a perceptible change for the rest of the year. The monthly averages, ranging within the low sub-epidemic limits of between 80% and 90% below the mean, are represented from September to December by what is virtually a straight line. The earlier September level, following the minor phase in the first year of epidemicity is also, almost with the same invariability, the lowest, after the initial stage and before that

It followed, therefore, that within each of three successive two-yearly spans into which the six years' notification period was divisible there were comprised an epidemic and a succeeding inter-epidemic period, each virtually complete. And this is so, as illustrated in the graphs whether the notifications for England and Wales, London and the Great Towns, counties such as Middlesex, the West Riding, Durham, Lancashire and Cheshire or great cities such as London, Manchester and Liverpool were severally subjected to such an analysis. While the course of a measles epidemic is thus displayed within a two-years' span, its actual duration falls well within that time. In none of the graphs does it exceed twenty months from the perceptible rise in January of the first year of epidemicity to its fall to sub-epidemic levels in August of the year following. And, indeed, there is little departure from this rule. It may, of course, be argued that within this span we are dealing, as has often been taken to be the case, not with a single, but with two epidemics. I think that the graphs render this view untenable, but this will be the better appreciated when we have considered more fully the features disclosed.

Epidemic beginnings.—The commencing point of each epidemic coincides approximately, as has just been said, with the beginning of the year of its initial development. But in the first, 1940–41, of the three series of epidemics which six years' notification has disclosed, already at the beginning of January a rise above sub-epidemic levels has been attained, but to a height which, if the curve be retrojected[1], places the start only a few weeks in advance of the commencing year. In the January, two years later, the level is a little lower and lower still, in fact barely perceptible, in the first month of the third two-yearly span. This means that each epidemic started just a little later in each succeeding epidemic period. This is not uniformly true of all the graphs, but is readily seen in those both of England and Wales (fig. 4*a*) and London and the Great Towns (fig. 2). The time of commencement does, presumably, make a difference to the subsequent development of an epidemic; the older it is, the sooner, *ceteris paribus*, its course is likely to be unfolded and completed. A procession of commencing dates and later developmental features in serial epidemics, should they, by more prolonged observations, be established, would greatly modify recurrent periodicities if they are, as they may be, chronologically, rather than seasonally, determined.

In the Statistical Review of the Registrar-General, 1921–25, attention is called to some notable changes in the seasonal curves of deaths from measles in which during a number of years "the gap between winter and spring peaks had filled up completely for London and almost completely for England and Wales. . . . The stages of this change for London are shown in the weekly returns from which it appears that in 1891–95 the February depression was pronounced, but that by 1911–15 its last traces had disappeared". It is the fact of these changes in peaks and gaps at the seasons named to which I wish to call attention. Neither the winter peak nor the February depression between it and the still surviving March maximum are generally to be recognized in the graphs of notifications with which we are dealing, though a cleft in the February of the major phase of the cases graph—England and Wales, 1942–43 epidemic (fig. 4*a*), and a similar depression corresponding in phase in the 1940–41 Durham epidemic (fig. 4*d*)—suggests that in these atavistic vagaries there may be a recent representative of the earlier notch. If over long periods certain valleys may be exalted and certain peaks laid low, the process, conceivably, may be one with a procession, a recession or an oscillation in the season of beginning epidemicity.

Epidemic phases.—The course of measles, graphed as above described, shows within each two-year span a minor and a major phase of epidemicity, separated by what I have called the autumnal notch and terminated by a spell of continuous sub-epidemic activity. Conformity to type is always a variable quantity and it is in accord with the proclivities of the typical that, in particular instances, wide departures may be shown amounting at times to total absence of a specific characteristic feature. In measles, epidemic types are no exception in their possession of aberrant members. For instance, the minor phase in the West Riding epidemic, 1944–45 (fig. 5, *see* p. 386), was wholly lacking and the epidemic, commencing in October, normally the eighth month of epidemic prevalence, continued thereafter in general conformity to the customary course, attaining its maximum in March—unlike its two predecessors with erratic maxima respectively in November and December—and completing its subsidence by August. But, lacking the minor phase, the epidemic is shortened to a single pinnacle of unwonted altitude, in this resembling the London epidemic of the same period where a minor phase, not lacking, but aborted, was followed by a similar pinnacle, the highest of any in the epidemics examined. Again in Manchester in the epidemic, 1940–41 (fig. 4*c*), the minor phase commencing late was merged completely with that of the major, the dividing autumnal notch being wholly absent and the customary low incidence of August replaced by a maximum peak in which the only tribute to the usual depression of

[1] Notification had come into operation only shortly before this and could not yet be said to have got into its stride.

not less than the striking, occasionally violent, outbursts which from time to time dominate attention.

In measles, a just-continuing persistence, in whooping cough, an apparently erratic sub-epidemicity, are the reservoirs from which spring the spectacular outbreaks apt to monopolize observation to the neglect of the no less important, though less obtrusive, modes of prevalence.

Not apparently seasonally determined, though, as seen in the measles graphs, regularly from September to December, in alternate years, seasonally exhibited, they are an enduring source from which, when circumstances favour, are started the rising prevalences that culminate in epidemics. Whooping cough shows little proclivity to regular periodicity either in its general or inter-epidemic features and measles, in this phase of prolonged quiescence, is in contrast with its seasonal behaviour in alternate years, when, in the same months, following the autumnal notch, there is, normally, a rapid and continuing rise to epidemic heights.

It cannot be that identical months exhibit seasonal influence in so diverse a manner, and alternating seasonal exhibition of these opposed phases of incidence can mean only that they are determined otherwise than by seasonal influences. But the significance of the continuing lowered incidence between epidemics of measles and whooping cough is that in this endemic diffusion the train is laid so that never are the potentially explosive foci arising with each cessation of epidemicity far removed from the smouldering embers so readily converted to igniting sparks.

In neither of these affections is there reason to believe that the *materies morbi* have an independent, extra-corporeal career. Proliferation of the virus is almost certainly synonymous with microbial cytogenesis within the bodies of its increasing victims. When Brownlee (*Proc. R. Soc. Med.*, 1919, 12, 77) speaking of measles announced that "An epidemic is due chiefly to the properties of the organism causing it and that the periodicity of epidemics which occur at regular intervals depends for the most part on the life-history of the organism" he may have been prepared to accept the proposition that there was no reason to believe that at any time in its life-history was the measles organism saprophytic, and, if this be so, the significance of endemic continuity needs no emphasis. And we may, in passing, inquire as to whether periodicities or other features of epidemics can properly be spoken of as determined mainly by the properties of the organism causing them or, conversely, as due to co-ordinate qualities, the necessary proportionate correlative vulnerability in the populations threatened. The antithesis is false, for apparent variations in virulence of the organism are meaningless save in terms of implicit constants of susceptibility or alternatively of corresponding changes in immunity of infected persons. Infective, susceptible—obverse aspects of the same phenomenon, how shall we say of either that it is the chief; upon which of two reciprocals, for the most part, depends a result to which both are indispensable? The cause of an epidemic is never wholly the diffusion of organisms of constant or changing pathogenicity, never alone an accumulation of relatively susceptible persons, but always the two together. Without one and the other you cannot have the resultant cases.

CONCLUSION

Though whooping cough and measles are kindred epidemiologically, in many of their features, clinically, they are most dissimilar. Measles, one of the exanthemata akin to smallpox with which its affinities are so close that for long the diseases remained undistinguished one from the other, is in a category removed from the non-eruptive disease that has taken its description from its mastering, paroxysmal cough. Initially more catarrhal, more sharply febrile, brief in its duration if uncomplicated, measles spends itself selectively in inflammatory epithelial lesions.

Whooping cough, more insidious in its onset, prolonged in its growing distress, less prone primarily to involve the tissues in extensive inflammatory changes, is almost devoid of pathological histology. Increasingly, as it matures, its symptomatology is that of neural disturbance. The paroxysmal neurosis dominates, sharing in wider, less terrorizing functional disturbances unaccompanied by perceptible structural neural changes, the selective toxins of whooping cough in this differing from those of diphtheria which so often result in late organic paralyses.

That two diseases, clinically so unlike, each presenting fundamental contrasts of behaviour, measles notably in its biennial cycles of recurrence, whooping cough in this and other respects in erratic disunity, should yet otherwise exhibit so close an epidemiological concert and together have travelled so far toward a common destiny, is an unexpected result from so strangely assorted a yoking. Preventive technique must aim not, as in such epidemic diseases for instance as typhus and typhoid, at attempting to prevent their prevalence, but reached with the final fall, in the whole course of epidemic prevalence, but unlike the fall in the September following, it is immediately, in October, followed by resumption of the ascent which had been interrupted by the autumnal notch. This difference in the behaviour of measles at the conclusion respectively of the minor and the major phases is, perhaps, as convincing an evidence that they are phases and not alternating minor and major epidemics, as any presented by the graphs. If the phases be conceded features of a single epidemic, biennial periodicity remains a suitable description of epidemic recurrences so related, even more appropriate because more embracing than when applied only to biennially recurring peaks separated by a void. On the other hand, if the minor phase be regarded as in no sense one of epidemic prevalence, either of one or of separate epidemics, it becomes a nondescript incidence, somehow relegated to sub-epidemic levels to which discernibly it rarely descends. Should one be able to rest in such a contradiction he would be free to regard the surviving major incidence exclusively as an epidemic, relatively short-lived and alternating with a year of non-epidemic mixed flat and undulating prevalence. This, usually, is what is meant by biennial periodicity. Yet again the minor phases as such may cease and, if enlarged and separated by definite sub-epidemicity from what follows, be regarded justly as completed epidemics. In that case, of course, biennial periodicity disappears and is replaced by annual recurrences. But in the graphs of incidence of recent years there is seen to be comprised within a single span of four-and-twenty months the proportioned phases not alone of epidemic prevalence but also of the low levels of intercurrent sub-epidemicity. Thus seen, periodicity ceases to be a biennial recurrence of punctual maxima and becomes a periodic repetition of like prevalences each in its due season, once within two years. Ultimately the present forms of measles prevalences may be shown to be, as presented, impermanent; they may prove to be transitional stages to or from such a form of biennial periodicity as, hitherto, for the most part, it has been conceived. If the movement be towards a single peaked form recurring biennially, the minor phase together with the autumnal notch will each disappear and be reduced to levels uniformly sub-epidemic; if away from such a biennially periodic type and towards that of annual recurrence, the minor phase will expand, the autumnal notch deepen, and there may thus emerge annually recurring epidemics separated by sub-epidemic phases, long and short in alternate years. Exceptional forms of prevalence among those examined may be said to be illustrative of either trend.

Epidemic behaviour of whooping cough.—So much for the serial distribution of measles: what of whooping cough? Similarly treated to exhibit features of prevalence, the graphs are not helpful. So far from conformity to design being established, type has not even emerged. In his account of the epidemiology of whooping cough, Professor Bradford Hill sets out the seasonal differences in deaths and, so far as then known, in cases. Except for the bearing upon them of seasonal case fatality, notification has added little, so far, to this aspect of whooping cough epidemiology. That the graphs suggest no law of incidence, no definite periodicity of recurrence, no characteristic case distribution and no rule in seasonal quiescence, may be due to the longer time-span required for their development. Certainly, neither in their annual nor in their biennial features do they show aught but a law unto themselves.

Dr. J. B. Russell, a former Medical Officer of Health of Glasgow, says (Public Health Administration in Glasgow. Studies in Epidemiology. Edited by A. K. Chalmers. Glasgow, 1905): "Estimated simply by the numbers of its victims, whooping cough is by a long way the most formidable infectious disease known to Glasgow. We might probably generalize and say the most formidable infectious disease of industrial cities. It shoots up into an epidemic at intervals of two to five years. . . . *But whooping cough never subsides to a low level. Its line of mean prevalence is high.*" This is true to-day. It is the high level of sub-epidemicity which is an outstanding feature of whooping cough, in the steady maintenance of which it contrasts with measles. Owing to this fact its endemicity is probably of more importance than its epidemic exacerbations recurring as they do at intervals normally much longer than those of measles. One sharply-defined epidemic only, and another of lower incidence, but more extended duration, occurred during the period (whooping cough graph, fig. 3). The first, commencing in April 1940, continued till the end of 1941, by which time it had fallen only to the mean level of six years' cases, having during the greater part of two years' epidemicity consistently maintained a high degree of prevalence. The second, commencing in December 1942, attained its first low peak in May 1943, and after a gradual decline and reascent, reached a slightly higher peak in May 1944, terminating as an epidemic by October of that year. For the rest of the six years, the incidence was that of a high endemicity, by no means of uniform level and subject to variations in weekly incidence not unlike those of its epidemic periods.

Inter-epidemic prevalence.—The low levels of incidence to which, between epidemics, whooping cough relatively and measles positively sink, have an interest for the epidemiologist

Value of Tomography in Lesions of the Main Bronchi and their Larger Sub-divisions

By STANLEY NOWELL, M.B., F.F.R., D.M.R.

TOMOGRAPHY of the bronchi to demonstrate neoplasm and other lesions of the bronchi has been employed for several years.

The late E. W. Twining was one of the pioneers of its use for this purpose in this country. Bush has described cases of bronchial neoplasm demonstrated by tomography.

Hartley (1946) pointed out that in the diagnosis of lung carcinoma, owing to the diverse appearances on direct X-ray examination, the diagnosis of neoplasm is difficult and often only inferential. Even bronchoscopy may not be entirely successful. He stated that tomography is exceedingly accurate in the demonstration of carcinoma involving the bronchial wall, that one can assess whether bronchial carcinoma or mediastinal tumour is present and even, in some cases, differentiate lymphadenoma from lymphosarcoma.

The value of tomography is inadequately realized in this country.

G. W. Holmes has stated that the diagnosis of bronchial carcinoma depends entirely on the demonstration of deformity or obstruction of a bronchus and points out the value of tomography in showing definitely that there is an obstructing lesion of a bronchus. The late Tudor Edwards in 1945 mentions this use of tomography and Maurice Weinbren, 1946, "Manual of Tomography," London, illustrates some cases.

I shall discuss the value of tomography in lesions of the main bronchi and their larger divisions.

In tomography of the normal bronchi it is possible to show the trachea, right and left main bronchi and both upper lobe bronchi as far as their main divisions.

The lower lobe bronchi are seen for about two inches down to their main divisions and the middle lobe bronchus is also seen.

In the lateral tomograph the lower main bronchus is seen also the pectoral and first dorsal. With suitable technique other smaller branches further out may be seen.

These are not usually all seen on one film since, owing to the varying densities, different techniques are necessary for the various parts of the thorax. A graduated aluminium filter has been found helpful. It prevents the lung fields from being blotted out when the mediastinum is adequately penetrated. By this means central and peripheral bronchi may be more easily shown on one film.

Lesions of or affecting the bronchi, if they are to be demonstrated by radiology, must cause some deformity of the lumen of the bronchus. These deformities usually give the following appearances: (1) Smooth narrowing; or (2) irregular nodular narrowing of the lumen; (3) projection of a single nodule into the lumen; (4) complete blockage of the bronchus, either V shaped or rounded; (5) the origin of the bronchus is blocked with only a small nick showing.

All of these changes are readily visible, on tomography, in the main bronchi and their larger divisions.

Lesions external to the bronchi may press on and deform them evenly or invade them. In the latter case the appearances are similar to intrinsic lesions.

These effects may be caused by a variety of lesions both benign and malignant, intrinsic and extrinsic.

INTRINSIC LESIONS

These are (1) *inflammatory lesions*, granulomatous in type. They are usually either tuberculous or syphilitic (gumma).

Tuberculous lesions are usually from a direct extension or inhalation implantation from a lung cavity, occasionally in children from a lymph node. Œdema and nodular tubercle-formation occur, causing local emphysema or atelectasis. Oechsli states that they might be demonstrated by tomography or lipiodol. In practice there is usually a lung lesionp resent—cavity or infiltration—to suggest the diagnosis..

Syphilis.—One of the three main types of syphilitic lesion of the lungs is the gumma. It is usually near the hilum, peribronchial. The clinical signs are mild and of insidious onset. Serology is positive and it responds to anti-specific therapy. Sputum is negative for tubercle bacilli and for fungus.

at cultivating the immunizing process of which they have ever been the active, and in this respect collectively speaking, beneficent agents. Until this can be reliably effected by the promising prophylaxis of the immunologists, the path of still further fostering the natural course, the diseases themselves exhibit must be followed. Since the passing of the Public Health Act of 1875 the annual mortality they exact has fallen for each from over 400 to about 30 per million population, unaccompanied, so far as we can judge, by any corresponding or even positive fall in prevalence. This, the most signal feature in their behaviour, brings into striking relief the epidemiological importance of their case-fatality and marks the goal of the inevitable partnership they have imposed upon the human race, a more benign schooling to their wellnigh universal endemic-epidemic sway.

Dr. J. Alison Glover: Colonel Butler has, I think, triumphantly vindicated the epidemiological value of the notification of both diseases. Its practical value has, of course, been somewhat obscured during the war years by the shortages in medical, nursing and health visitor staffs and will become more obvious as these are restored to full strength.

In the decennium in which I began to study medicine, on an average 12,500 persons died each year of measles, and 11,500 of whooping cough. In the decennium ended 1945 the corresponding averages were 986 and 1,284. These impressive figures represent the saving each year of many thousands of lives and also a much lower incidence of those complications which, even when they do not kill, so often permanently damage health. There is little doubt that the immediate deaths form only a part of the mortality ultimately due to these two diseases.

The case fatality of measles, though it has varied greatly in different epidemics, used to be reckoned at about 4%. In 1945, though this was an epidemic year and 446,828 cases were notified, it was only 0·16%, about one-seventh of the immediate fatality rate of whooping-cough in the same year. Contrast this with 1918 when a modified system of notification (of the first case only in each family) was enforced, 414,346 cases were then notified, though of course there were many more. The number of deaths was 9,856 (nearly fourteen times as many as in 1945). Even if we assume that on average two cases occurred in each family, though probably this would over-estimate the actual number, the fatality rate must have been many times as great as that of 1945[1]. Colonel Butler has pointed out the very interesting sex ratio in the relative mortalities of the two diseases. It is an interesting point which I have not seen emphasized elsewhere that another disease, bacillary dysentery, resembles measles in that male infants and young boys show a higher notification of, and a much higher mortality from, dysentery than female infants and young girls, although in dysentery this higher young male incidence is much more pronounced and persists to a later age.

Value of Tomography in Lesions of the Main Bronchi and their Larger Sub-divisions

By STANLEY NOWELL, M.B., F.F.R., D.M.R.

TOMOGRAPHY of the bronchi to demonstrate neoplasm and other lesions of the bronchi has been employed for several years.

The late E. W. Twining was one of the pioneers of its use for this purpose in this country. Bush has described cases of bronchial neoplasm demonstrated by tomography.

Hartley (1946) pointed out that in the diagnosis of lung carcinoma, owing to the diverse appearances on direct X-ray examination, the diagnosis of neoplasm is difficult and often only inferential. Even bronchoscopy may not be entirely successful. He stated that tomography is exceedingly accurate in the demonstration of carcinoma involving the bronchial wall, that one can assess whether bronchial carcinoma or mediastinal tumour is present and even, in some cases, differentiate lymphadenoma from lymphosarcoma.

The value of tomography is inadequately realized in this country.

G. W. Holmes has stated that the diagnosis of bronchial carcinoma depends entirely on the demonstration of deformity or obstruction of a bronchus and points out the value of tomography in showing definitely that there is an obstructing lesion of a bronchus. The late Tudor Edwards in 1945 mentions this use of tomography and Maurice Weinbren, 1946, "Manual of Tomography," London, illustrates some cases.

I shall discuss the value of tomography in lesions of the main bronchi and their larger divisions.

In tomography of the normal bronchi it is possible to show the trachea, right and left main bronchi and both upper lobe bronchi as far as their main divisions.

The lower lobe bronchi are seen for about two inches down to their main divisions and the middle lobe bronchus is also seen.

In the lateral tomograph the lower main bronchus is seen also the pectoral and first dorsal. With suitable technique other smaller branches further out may be seen.

These are not usually all seen on one film since, owing to the varying densities, different techniques are necessary for the various parts of the thorax. A graduated aluminium filter has been found helpful. It prevents the lung fields from being blotted out when the mediastinum is adequately penetrated. By this means central and peripheral bronchi may be more easily shown on one film.

Lesions of or affecting the bronchi, if they are to be demonstrated by radiology, must cause some deformity of the lumen of the bronchus. These deformities usually give the following appearances: (1) Smooth narrowing; or (2) irregular nodular narrowing of the lumen; (3) projection of a single nodule into the lumen; (4) complete blockage of the bronchus, either V shaped or rounded; (5) the origin of the bronchus is blocked with only a small nick showing.

All of these changes are readily visible, on tomography, in the main bronchi and their larger divisions.

Lesions external to the bronchi may press on and deform them evenly or invade them. In the latter case the appearances are similar to intrinsic lesions.

These effects may be caused by a variety of lesions both benign and malignant, intrinsic and extrinsic.

INTRINSIC LESIONS

These are (1) *inflammatory lesions*, granulomatous in type. They are usually either tuberculous or syphilitic (gumma).

Tuberculous lesions are usually from a direct extension or inhalation implantation from a lung cavity, occasionally in children from a lymph node. Œdema and nodular tubercle-formation occur, causing local emphysema or atelectasis. Oechsli states that they might be demonstrated by tomography or lipiodol. In practice there is usually a lung lesionp resent—cavity or infiltration—to suggest the diagnosis..

Syphilis.—One of the three main types of syphilitic lesion of the lungs is the gumma. It is usually near the hilum, peribronchial. The clinical signs are mild and of insidious onset. Serology is positive and it responds to anti-specific therapy. Sputum is negative for tubercle bacilli and for fungus.

Male, aged 57. Admitted as ? perforation. Referred for barium meal. This was negative. At barium meal the left lower lobe was seen to be collapsed. Wassermann strongly positive.

Subsequent tomograms showed a narrowing of the left lower main bronchus just below the upper lobe branch (figs. 1 and 1A).

In the lateral tomogram the narrowing is clearly seen for a cm. or so (figs. 2 and 2A). This was confirmed by bronchoscopy where the narrowing was again seen. The wall was like old granulation tissue, with pale mucous membrane, uniform surface with no bleeding or oozing. ? a gumma.

FIG. 2.—Same patient. Lateral view.

FIGS. 1A and 2A.—Diagram of tomograms showing narrowing of the left lower lobe bronchus just below first dorsal origin. The narrowing is clearly demonstrated in the lateral tomogram.

He was treated with anti-specific therapy with much clinical improvement in two months. A direct film taken three months later showed the left lower lobe was nearly fully expanded.

A few months later he was admitted to the mental hospital as a case of general paresis. A film then showed the left lower lobe to be fully expanded.

A case similar to this, with post-mortem confirmation, was described by Stevens and Hudson in 1934 (not tomogram).

Pearson cites lobar atelectasis occurring in syphilis.

(2). *Neoplasms.*—Benign and some types of *malignant neoplasms* produce the appearance of type three or four in the bronchus (*see* previous list)

Bronchoscopy is necessary to differentiate and section is advisable since an adenoma may be malignant.

Malignant neoplasms may give any of the five types of deformity but types four and five are, I think, usually definite evidence of a carcinoma bronchus.

If one bronchus is not seen my experience is that the finding must be ignored and the examination repeated. It is usually due to a technical fault. However if one bronchus is not seen but the adjacent larger or smaller bronchus shows a narrowing or deformity, then the findings may be accepted as a definite bronchial block with invasion of the adjacent bronchi as demonstrated. The following cases show well such a condition.

W. (fig. 3).—Collapse of left lower lobe. Tomogram: Left lower lobe bronchus not seen. Left main narrowed and deformed. Infiltrating neoplasm of bronchus. Patient died three months later.

R. O. (figs. 4 and 4A, and 5 and 5A).—Left lower lobe bronchus not seen on tomogram. Left

These show the extent of invasion which may be present without collapse or even much hilar increase.

Any case with the least suspicion of carcinoma should be tomographed.

Tomography in More Peripheral Lesions

In the more peripheral lesions a malignant infiltration will invade the smaller bronchi and cause narrowing in parts. The following cases show such invasion:

D. M/62.—Weakness, cough, weight loss. Direct: Patchy infiltration in axillary segment. Tomogram: Right upper and lower main bronchi well seen and clear. Junction of right axillary and apical ill-defined. Axillary narrow. Probably carcinoma with lymphatic spread. Post-mortem: Carcinoma at site shown. Two small liver metastases.

R. M. M/57.—Weight loss. B.S.R. 104. No definite chest symptoms. Left sciatic pain one week. Direct: Irregular shadow close to right hilum just posterior to mid-plane (fig. 6). Tomogram: Apical branch is distorted and irregular. Opinion that it is a malignant lesion on these grounds (fig. 6A). One month later right lower lobe commencing collapse. Diaphragm rising, right. Died. No post-mortem allowed.

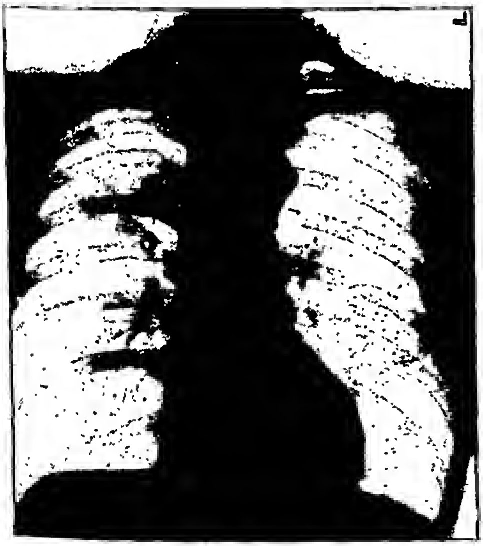

FIG. 6.

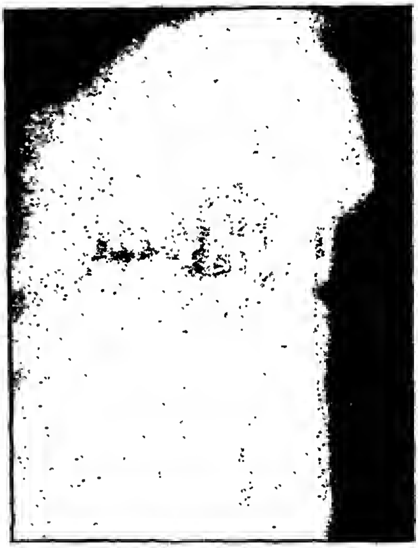

FIG. 6A.

FIG. 6 (Case R. M.).—Direct film. Irregular fairly well defined shadow close to right hilum and just posterior to mid-plane.

FIG. 6A.—Tomogram of case in fig. 6. Irregularity and distortion of the right apical branch is demonstrated. This branch is lying in the shadow.

R. J. M/62.—Silicotic; on compensation. From S. Africa. Direct film: Shadow 2 cm. size in upper lobe just anterior to main bronchi. D.9 collapsed and erosion in twelfth rib head.

Tomogram: Main bronchi clear. Apical and axillary bronchi not narrowed or distorted, though they are lying just behind and close to the shadow. In a lateral tomogram the pectoral branch is seen just below the shadow in the same plane. It shows no narrowing or displacement. Probably a malignant alveolar lung lesion.

At post-mortem a necrotic tumour, microscopically a carcinoma, was found at the site of the shadow. The bone lesions were secondaries.

The view is put forward that if a lung infiltration is malignant the bronchi close to or in it will be narrowed in parts and some blocked. In a case of tuberculosis they were not so affected and the infiltration was more discrete on tomography.

With small or medium-sized tumour shadows in the lungs, clear of the main bronchi, tomography may be helpful, if the shadows of the smaller bronchi are studied. With a upper lobe bronchus a little irregular. Note, however, that the irregular blockage of the left lower lobe bronchus is shown in the lateral tomogram. If not seen in an a.p. tomogram narrowing of a lower main bronchus may be seen in a lateral tomogram. Often the whole length of the narrowing and irregularity of the lumen is seen in a lateral tomogram.

Tomograms also often disclose invasion around adjacent main bronchi and even the main bronchus of the opposite side may be invaded. Such wide invasion was shown by tomography in the following case.

C.—Was admitted with œsophageal obstruction. There was an infiltrative lesion of the œsophagus. It was also noted that the left lower lobe was collapsed.

Tomograms showed blocking of the left lower bronchus and infiltration of right and left main bronchi.

Post-mortem confirmation of bronchial carcinoma with secondary spread and invasion of outer walls of œsophagus.

On tomography alone I know of no method of absolutely distinguishing an inflammatory lesion or benign or malignant neoplasm of the bronchi. Even bronchoscopy may not be able definitely to decide. However, from tomography very suggestive evidence is obtained.

(1) A single nodule is a neoplasm, benign or malignant. (2) A complete V block, especially at origin is almost certainly a bronchial carcinoma. (3) A bronchus not seen, but adjacent bronchi narrowed, is a malignant growth with wide spread. (4) A narrowed bronchus with other bronchi also narrowed means a carcinoma with wide spread.

This is a measure of the value of tomography in assessing amount of invasion.

EXTRINSIC LESIONS

These are mainly glandular; Hodgkin's disease, lymphosarcoma, leukæmias, &c., and also thymic tumours and benign mediastinal tumours.

These usually cause extrinsic pressure effects. If no bronchial invasion is seen then a malignant lesion of the bronchus can be ruled out, and the diagnosis of mediastinal tumour made on other radiological and clinical grounds. Possibly the tomogram may bring to light some faint calcification not previously seen, suggestive of dermoid.

Hartley (1946) pointed out that lymphosarcoma, though extensive, does not commonly compress or invade the bronchi, whereas Hodgkin's disease usually displaces or compresses the bronchi. By such signs a differential diagnosis is possible.

However, both of these can invade the bronchi causing a granulomatous occlusion and atelectasis. In such cases the appearances are those of intrinsic invasion and even the extent of invasion is no guide since bronchial carcinoma, as previously demonstrated, may have wide invasion. However, with malignant mediastinal tumour the invasion, one finds, is usually more hazy and ill-defined, often with gross distortion of channels.

Tomography in Bronchial Lesions with No Lobar Collapse

Nearly all the cases so far have been fairly obvious, having gross atelectasis or large shadows. Even in such cases tomography may give the exact cause of the atelectasis or, conversely, rule out a bronchial neoplasm.

Even when there is no real atelectasis and slight dubious hilar enlargement and possibly a little hæmoptysis tomography can very definitely help.

About 10% of all ultimately proved carcinoma bronchi will be seen in this early stage, so it is important to do tomograms on them. Cases of this type are described.

H. J. M/46.—Few months slight dyspnœa. Recent slight hæmoptysis. Direct film: Irregular, not very dense increase in right hilum. No lobar collapse.

Tomograms: Irregular narrowing of right lower main bronchus for ½ in. above right middle. Well seen on lateral tomogram where slit-like narrowing is shown.

Bronchoscopy: papilliferous tumour at site. Thoracotomy and pneumonectomy. Tumour could not be completely removed. Died a year later.

J. G. M/47.—Dyspnœa 4/12. Chest pain. No hæmoptysis. Direct: Left hilum enlarged, fine processes from it. No collapse of lobes.

Tomogram: Left main narrowed and irregular. A more extensive lesion than one would expect is shown.

He soon developed an abscess and later bronchial obstruction.

time he could be quickly transferred to the person or department most suitable. On the other hand, if a patient could be shown quickly to have a tumour involving the mediastinum, with no evidence of primary lung disease and a presumptive diagnosis excluding benign tumours and cysts, such a case could be readily dealt with by the radiotherapists; for radiation therapy would be likely not only to prove beneficial but to be of diagnostic value. since the nature of the response of the tumour to radiation afforded this information. In other words in cancer treatment it was sometimes more important to decide quickly whether or not to treat the patient than it was to establish the exact academic diagnosis.

Dr. R. Kemp Harper disagreed with the statement made by Dr. Peter Kerley that tomography was of little value in the diagnosis of peripheral carcinoma of the lung. He pointed out that the size, position, density and limits of the opacity in the lung could be more clearly defined by the use of tomography, and all these points were of great importance in differentiation. In connexion with the diagnosis of enlarged tracheobronchial glands secondary to carcinoma of the lung, he drew attention to the fairly constant appearance of a smooth oval or circular density at the right tracheobronchial angle which was caused by the azygos vein and should not be mistaken for an enlarged gland.

Dr. Thomas Lodge suggested that it was well to remember that there were other structures in the lung besides the bronchi and that different tomographic techniques in a given case should be employed in order to demonstrate the other structures, for example, the displacement of the lung vessels by benign tumours.

Dr. A. Elkeles (in reply): The described pulmonary changes associated with mitral stenosis are not so rare as Dr. Kerley suggests. Since cardiologists usually obtain their information by screening only, these pulmonary nodular infiltrations may have easily escaped recognition. Furthermore these calcified nodular infiltrations have been interpreted in the past as calcified tuberculosis. Evidence can be found in the literature of such cases having been sent unnecessarily for prolonged sanatorium treatment.

My second patient and some cases described in the literature showed no clinical or radiological evidence of pulmonary congestion, which invalidates the theory that these bony nodules are the result of long-standing passive congestion. The history of rheumatic pneumonia and pleurisy in these patients and in particular the microscopic findings of specific rheumatic changes in the lungs are in support of our theory of these ossified nodules being the late stage of rheumatic pneumonia.

I agree with Dr. Lodge's remarks, that the lung changes are primarily vascular in nature, which lends further support to the theory, that rheumatic fever belongs probably to the more severe type of vascular allergy.

Disseminated Ossified Nodules in the Lungs Associated with Mitral Stenosis

By A. Elkeles, M.D.

Nodular calcifications in the lungs are generally interpreted as evidence of healed primary or post-primary tuberculosis. Recent investigations by mass-radiography indicate that this current concept of pulmonary calcifications may have to be revised at least to some extent. Pulmonary calcifications were found in a considerable number of cases, in which no evidence of past or present tuberculosis could be found, and in which the Mantoux test proved negative. As causative agents of the so-called non-tuberculous calcifications in the lungs, infection with *Ascaris lumbricoides*, coccidiomycosis and aspergillosis have been suggested, but convincing evidence for this assumption is still lacking. Zwerling and Palmer (1946) on examining a total of 6,199 student nurses by mass-radiography in the central eastern states of America, found pulmonary calcifications in 698. These authors suggest that infection with *Histoplasma capsulatum* may be responsible for a large number of pulmonary calcifications and base their assumption mainly on the result of skin tests. These revealed that 494 out of 698 cases were histoplasmin positive, whereas only 57 were tuberculin positive and 109 positive to histoplasmin and tuberculin, the remaining 38 were negative to both. Whether Palmer's findings may only apply to certain areas in the United States, where infection with *Histoplasma capsulatum* may be prevalent, or whether it will prove to be of wider significance, remains to be seen, when mass-radiography will be performed on a wider scale.

The purpose of this paper is to draw attention to a special type of pulmonary nodular calcifications occasionally met with in mitral stenosis. Although the X-ray appearances show a close resemblance to calcified pulmonary tuberculosis caused by hæmatogenous spread, the macroscopical and microscopical examination of the lung in these cases reveal no evidence of tuberculosis and most of the nodular lesions were found to consist of true bone.

E. Wagner was the first to report on bone formations in the lungs as far back as 1859, when he published a case of a female, 25 years of age, who died of dropsy and in whom he found numerous bones in the lungs. In 1862 Heschl published a paper on osteoides in the non-malignant tumour the bronchi close to the shadow will be displaced away from the shadow. If the shadow is due to a malignant tumour the bronchi running through it are narrowed or occluded due to invasion. Those close to it are neither displaced nor narrowed.

An exception to this is a chronic abscess. In one case with a chronic thick-walled abscess, proved by operation, the tomogram shows a severe narrowing of the left upper lobe bronchus below the main shadow, close to the origin of this bronchus. This was misinterpreted at the time as a carcinoma of the upper lobe. The explanation appears to be that in contracting the abscess had constricted the upper lobe bronchus by fibrous bands surrounding it.

CONCLUSIONS

By the use of tomography in both antero-posterior and lateral planes and by varying technique and methods to suit the individual case a good view of the main bronchi and many of the smaller bronchi may be obtained without disturbance to the patient and without introducing opaque media into the bronchi.

With the bronchi thus visualized changes in their lumen from intrinsic or extrinsic lesions are demonstrable. In many cases the changes so demonstrated are a sufficient basis for a definite diagnosis. However, in general, bronchoscopy is necessary to determine the nature of the lesion. Tomography and bronchoscopy are thus complementary. Tomography is, however, of great value in demonstrating the site of a lesion prior to bronchoscopy and in cases where bronchoscopy is negative tomography may demonstrate a lesion.

Tomography is valuable in showing the extent of invasion of the bronchi, invasion of adjacent and even the contralateral bronchus being demonstrable.. It may be of great value in differentiating various types of mediastinal lesions.

If the smaller bronchi are adequately studied by tomography a valuable clue as to the nature of more peripheral lung lesions may be obtained. In such cases careful attention must be given to these bronchi to see whether they are narrowed, blocked, distorted or displaced.

In cases which show a slight or moderate hilar enlargement with no lobar collapse or even no commencing atelectasis tomography is of extreme value. In such cases it will very often demonstrate a lesion of the main bronchus, showing both the site and extent of the lesion and very often giving a valuable clue as to its nature.

Dr. G. Simon inquired whether the speaker had found tomography of any value in deciding on the operability or otherwise of pulmonary neoplasms.

Dr. P. Kerley; Accurate tomography requires a considerable amount of time and the personal attention of a radiologist. It can be of help in some cases of malignant disease of the lungs, but I would not agree that it should be employed as a primary diagnostic measure.

The lung is one of the commonest sites of carcinoma in men and the only prospect of cure lies in early surgery. Bronchoscopy is by far the quickest and most reliable method of establishing a diagnosis once suspicion of the condition is raised, either by symptoms or the finding of an abnormal radiological shadow.

I find tomography of more help in seeking for unsuspected enlarged mediastinal glands secondary to primary carcinoma of the lung.

Dr. J. Blair Hartley expressed the view that although tomography required the same personal attention to the case, and frequently formed but part of the very detailed investigations necessary, nevertheless it was incorrect to assume that carefully-devised routine tomographic investigations were not often of the greatest value. One knew, from experience in a very large number of cases, the levels between which the mediastinal shadow and the trachea and main bronchi must lie. A series of sections taken through this "area" must, therefore, produce information concerning the position and appearance of the major bronchi. Thus, it is frequently possible to determine, within a few moments, whether an acknowledged tumour is of mediastinal or pulmonary origin. In a large radiotherapy centre it was not always necessary to make a precise diagnosis before dealing with the case, for if a patient could be rapidly shown to be untreatable by radiation therapy, instead of wasting spread to different parts of the lungs by hæmoptysis. Since there is neither evidence of cavitation nor any history of hæmoptysis, it may reasonably be assumed that the widespread calcified nodular infiltrations are of the same type as in the previous case. Furthermore the diagnosis of pneumonia and pleurisy by her doctors during the acute attack of rheumatic fever suggests that according to our present knowledge the patient was suffering from rheumatic pneumonitis and pleurisy. The same probably applies to Derischanoff's case, who suffered from severe pneumonia for over two and a half months, four years prior to his admission to hospital. The history of pneumonia during the course of rheumatic fever may be taken as further evidence in support of our theory that ossified pulmonary nodules in rheumatic valvular disease are the late results of rheumatic pneumonitis.

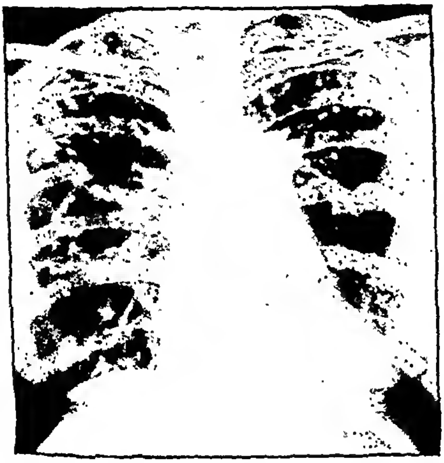

FIG. 1.—Mitral stenosis with disseminated nodular spacities in both lung fields.

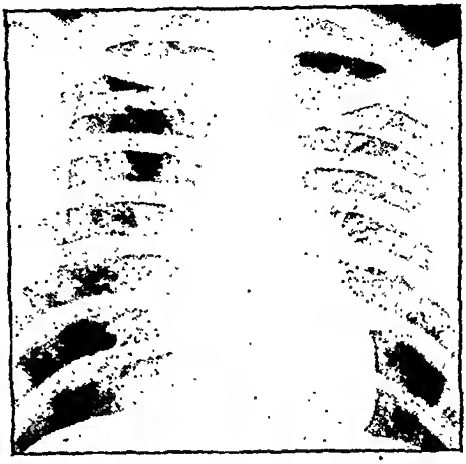

FIG. 2.—Chronic calcified miliary pulmonary tuberculosis.

With regard to the radiological diagnosis of the pulmonary lesions, it is obvious that calcified nodular infiltrations as such do not represent a characteristic feature, as they may be met with in other conditions. Indeed the pulmonary lesions show a certain resemblance to calcified chronic miliary tuberculosis. It is in particular the association of the pulmonary lesions with mitral stenosis which should raise doubts as to the tuberculous character of the nodular calcifications. Pulmonary tuberculosis is a common complication in congenital heart disease, but is only rarely met with in mitral stenosis. The absence of extensive calcified mediastinal glands or of post-primary parent lesion or lesions in the lungs may also be taken as evidence against the tuberculous character of the calcified nodules.

Since calcified miliary tuberculosis is extremely rare, strong evidence for the tuberculous origin of miliary, pulmonary calcifications is required as for instance the detection of tubercle bacilli or calcified nodules in spleen, liver or other organs or the involvement of skin, bones, joints or genito-urinary tract, &c.

In the following case we can compare the pulmonary lesions of calcified miliary tuberculosis with those of the calcified nodules in mitral stenosis.

Male, 34 years of age, has a history and radiological evidence of healed tuberculosis of the right hip-joint, and a still active tuberculosis of the right shoulder-joint with a discharging sinus. Radiogram of his chest taken on 13.12.46 reveals numerous, minute shot-like calcareous deposits in both lungs, which show an almost symmetrical distribution over the middle and upper lung fields. An old Ghon's focus is seen in the left lower zone with calcification of the draining hilar glands. The left costophrenic angle is slightly obscured and suggestive of healed pleurisy (fig. 2).

The distinguishing features of the chest radiograms of the two conditions are:

In mitral stenosis.—The calcified nodules vary from pinhead to large pea size. They show various shades of density, are not always discrete and have a tendency to coalesce. The nodules are distributed over the central lung fields as well as the periphery.

lungs in a male 26 years old with chronic endocarditis. Derischanoff in 1930 described a case of a male 21 years of age, who died of cardiac failure due to mitral stenosis and incompetence. On post-mortem examination multiple tuberous osteomata were found in both lungs, more numerous in the lower lobes, but also present in both apices. Four years prior to his admission to hospital he had suffered from pneumonia lasting for over two and a half months. Salinger (1932) was the first to recognize the relationship of pulmonary bony nodules and mitral stenosis. In recent years several cases of this strange co-existence have been reported in the American and continental literature. The only case published so far in this country is by Elkeles and Glynn (1946). In this paper evidence was produced for the probability of the pulmonary ossified nodules to be the end-result of rheumatic pneumonia and not, as hitherto believed, the outcome of long-standing passive congestion of the lungs in mitral stenosis.

The patient was 32 years of age and suffering from advanced mitral stenosis with auricular fibrillation and passive congestion of the lungs. Chest radiograms confirmed the clinical diagnosis of mitral stenosis with passive pulmonary congestion. Both lung fields were scattered with numerous densely opaque nodules of pinhead to small pea size. The right lower lobe was predominantly involved and particularly its periphery. The nodules were well defined and the larger ones were mulberry-like in shape. No nodular infiltrations were seen in the apices. No calcified mediastinal glands and no evidence of primary or post-primary lesion or lesions were present. The radiological diagnosis of non-tuberculous calcified bony nodules associated with mitral stenosis was confirmed by post-mortem examination nine months later. The microscopical examination of the pulmonary nodules proved them to consist of bone of the woven type and intra-alveolar in position.

Bone formation in the lungs is occasionally met with in old men, but the bone is formed in the interstitial tissue and not in the parenchyma of the lung. Pulmonary ossification is often met with in healed primary tuberculous lesions. In the primary focus the central area undergoes caseation and destroys the elastic framework of the lung and healing proceeds by the deposit of calcium salts in the caseous material, bone tissue is formed in the periphery from the specific connective tissue by metaplasia, thus creating a bony shell, which walls off the diseased area. The healed primary focus can therefore be distinguished on microscopical examination from the ossified nodules in mitral stenosis by the destruction of the elastic framework of the affected area and by marginal ossification.

It is likely that the described pulmonary lesions have in the past often been interpreted as calcified tuberculosis on chest radiograms.

The second case to be reported here confirms this assumption.

A female, 43 years old, had severe tonsillitis at the age of 9 followed by rheumatic fever and complicated by pneumonia and pleurisy and valvular disease of the heart. When over fourteen years ago the first X-ray of the chest was taken, her lungs showed evidence of widespread calcified nodular infiltrations, which were then interpreted as healed pulmonary tuberculosis. No tubercle bacilli could be found in frequent sputum examinations. A radiogram of her chest taken in July 1946 shows a small aortic knob, a prominent pulmonary conus and an enlarged pulmonary artery, straightening of the middle segment of the left cardiac border. The left ventricle is somewhat enlarged, which may, however, only be apparent owing to the rotation of the heart, which sometimes takes place in right ventricular enlargement. Both lung fields are scattered with numerous nodules of varying density, size and shape. The nodular opacities are most widespread in the upper zones, even involving the apices. The middle zones show somewhat less involvement, and some nodules are visible in the region of the right cardiophrenic angle. The left lower zone is almost clear. The nodules vary from a pinhead to a pea. On close inspection many of the small nodules are round and discrete, the larger ones are often mulberry-like in shape and some have translucent areas in their centre, others coalesce with neighbouring nodules. Much fibrosis is visible in the upper zone. Calcified hilar glands are conspicuously absent (fig. 1).

Clinically the patient has a loud rumbling diastolic murmur with presystolic accentuation at the apex, P2 is accentuated. An E.C.G. reveals right preponderance and flattening of T waves in lead 3. The loud diastolic murmur as such is no indication of the severity of mitral stenosis. The patient shows no evidence of cardiac failure and is leading an active life; she is still able to climb three flights of stairs without appreciable dyspnœa. The patient has no history of pulmonary or extra-pulmonary tuberculosis. The absence of calcified hilar glands makes the pulmonary lesions unlikely to be the result of a primary infection. Widespread dissemination of tuberculous lesions in the lungs arising from post-primary infection, whether hæmatogenous or bronchogenic, originate mainly from cavitation or are

JOINT DISCUSSION No. 2

[*January* 1, 1947]

DISCUSSION ON THE TREATMENT OF CANCER OF THE TONGUE

Sir Stanford Cade: My remarks are based on the observation of about 550 patients with malignant lesions in the mouth; of these, 380 were primarily tongue lesions. The period covered is just under thirty years and it is twenty-two years since I first used radium in the treatment of lingual cancer.

What is our knowledge to-day of cancer of the tongue as a disease entity? What are the accepted forms of treatment, and what hope is there for a patient to survive to his allotted span?

Cancer of the tongue has undergone a change in its natural history in our generation, but evolutionary changes are slow and, to those who are part of them, imperceptible. It may therefore be useful to reflect on the main changes. This disease was usually associated with poverty—it is by no means exclusively so to-day, although its association with bad oral hygiene and gross dental sepsis remains of ætiological significance. The sex incidence in the past twenty years has altered from a 10% incidence in women to nearly 20% of the total number of cases of cancer of the tongue, and in some countries, for instance Sweden, it is nearly 40%. The incidence of the disease has shown a decline for the past thirty-five years, but not simultaneously in all age-groups; thus at ages under 65 the decline has been continuous since 1911, but for the 65 to 74 decade it did not begin till 1935; and not till 1940 was a fall registered in the age-group of 75 and over.

There is thus a relative and an absolute diminution in the incidence of the disease which is now the lowest in incidence of all sites. In England and Wales about 1,000 deaths a year are registered as due to cancer of the tongue; the computation of patients alive with the disease is very much more difficult; but even if the totals reach three times that figure, there are only 75 cases of cancer of the tongue to every million living persons. This low incidence has a great bearing on the organization of the treatment, if adequate treatment only is to be offered.

Factors which determine the choice of treatment.—The important factors which determine the choice and technique of treatment are the *site, extent,* and macroscopical *type* of the lesion; to a lesser extent the histological classification of the degree of malignancy. The presence or absence of enlarged cervical nodes vitally affects the prognosis but does not *per se* determine the treatment of the primary growth.

It is no longer necessary to emphasize that radiation is the first choice as a therapeutic measure for the primary growth. It is more profitable to indicate the place of surgery; it is also simpler to do so as the field of surgery has narrowed down to a few, well-defined indications. Providing adequate facilities and trained personnel are available, the primary lesion in all cases of cancer of the tongue should be treated by radiation with the exception of the following: (1) Where the lesion has transgressed the floor of the mouth and involved the mandible. (2) Where the entire tongue is involved in its anterior part down to the V of the circumvallate papillæ by a hard infiltrating growth. (3) In cases which have failed to respond to radiation either as an immediate failure with but slight regression of the lesion; or when recurrence of active disease takes place within a few months of treatment.

It should be noted that the earlier the lesion, the more suitable it is for radiation;

In calcified miliary tuberculosis.—The calcified nodules are discrete and more uniform in size and density. They mainly involve the central lung fields. There is usually evidence of primary or post-primary tuberculous lesions.

There are several other conditions in which calcified nodular opacities in the lungs may occur, e.g. pneumoconiosis, calcium metastasis, pneumomycosis, pulmonary hæmosiderosis and sarcoidosis, the history, clinical picture and laboratory investigations should assist in the differential diagnosis. Finally the miliary type of long-standing passive congestion of the lungs in mitral stenosis will be mentioned. According to Peter Kerley the combination of swollen end-on vessels and alveoli filled with heart-failure cells are responsible for the nodular opacities. Since the pulmonary vessels decrease in size towards the periphery, there is a corresponding decrease in the size of the spots, a feature which should help in the differential diagnosis from other miliary lesions and in particular from the above-described pulmonary lesions in mitral stenosis.

The described pulmonary changes in rheumatic valvular disease are not only of diagnostic interest, but if our theory of the pathogenesis of the ossified nodules could be confirmed, it would be further proof of the existence of specific rheumatic manifestations in the lungs.

POSTSCRIPT (6.5.47).—A third personal case has just been observed which shows the same nodular calcified pulmonary infiltrations in a long-standing case of mitral stenosis.

Dr. P. Kerley: There should be a very sharp differentiation between calcified nodules and ossified nodules. In the case described by Dr. Elkeles the nodules were composed of true osseous tissue. Calcification occurs in the absence of a good blood supply.

We know from observation of traumatic vascular injuries that bone stimulation occurs with chronic venous stasis. I think this is a prominent factor in the development of osseous nodules in mitral stenosis. I would not agree that the infective agent in rheumatic fever is responsible for the osseous formation, since the condition is so rare and has not been described in aortic lesions of rheumatic origin.

Dr. Thomas Lodge thought that Dr. Elkeles had put his finger on the key to the problem in many cases of unusual opacity in the lung either calcareous or ossified nodules or even iron pigmentation. The pathologists now felt that there was a primary rheumatic condition of lung vessels not always associated with rheumatic endocarditis, and that changes in the intima of the vessels might lead to increased permeability to calcium and to the deposition of calcified and ossified nodules in the lung.
